The authors wish to thank Taninos da Acácia S.A. (TANAC®) for the donation of the industrial tannin extract, as well as Dr. John Kennedy Guedes Rodrigues and Mr. Eduardo Tenório (Laboratório de Engenharia de Pavimentos/UFCG) for the mechanical tests. Also, we would like to acknowledge the English revision of Miss Bia Carneiro.
Abstract

*Mimosa tenuiflora* (Willd.) (MT) Poir. is an underutilized plant species since its wood is mostly used for energy production. Nonetheless, the bark from this forest plant has a high amount of tannins and other valuable compounds. Tannins have high worldwide importance and, because of that, there is an increasing number of researches on biorefinery systems aiming at maximizing their exploitation. The present study evaluated tannins extracted from the MT bark and their use for producing wood adhesives. Three types of powdered tannins were extracted using different solvents: a pure aqueous solution, a 5% sodium hydroxide (NaOH) aqueous solution, and a 5% sodium bisulfite (NaHSO₃) aqueous solution. Also, distilled water, wheat flour, and formaldehyde were used as a solvent, a glue extender, and a catalyst, respectively. These adhesives were applied for bonding pine wood joints and their shear strengths were determined. All the MT-based adhesives showed high viscosities and, if compared to each other, yielded glue lines with similar shear strengths and similar shear deformations. That tannin-based glue incorporated with the tannin extracted using NaOH/NaHSO₃ stood out and yielded a similar bonding performance compared to a commercial adhesive applied as a positive control.

Introduction

Located at the semi-arid Brazilian region, the caatinga vegetation has a restricted timber production for several commercial purposes, such as furniture, lumbers, and civil engineering. Most of these available trees have high tortuosities and are overturned before developing high diameters. Therefore, sustainable management of non-timber forest products (NTFPs) emerges as an important complementary alternative for some communities, which depend on this biome to survive.

In the last decades, the concept of sustainability has gained prominence, especially after the Rio-92 Conference. This term can be briefly defined as the ability of humans to use available resources and meet their current needs, preserving the ability of future generations in also meeting their needs. According to the Brazilian Institute of Geography and Statistics – IBGE [1], NTFPs have been progressively exploited in Brazil and reached their highest production value in 2018. For instance, açai berry (R$ 592.0 million), yerba mate (R$ 468.4 million), Brazil nuts (R$ 130.9 million), carnauba wax (R$ 189.2 million), and babassu almonds (R$ 92.1 million) also reached outstanding production values in their respective markets.

Vegetable tannins (natural polyphenolic compounds) also stand out for their high market values (0.7-1.5
Among these resources, condensed tannins are responsible for the largest global production (about 90%) with about 200 thousand tons per year [3-4]. For this reason, numerous forest species have been used as matrices for extracting tannins, including Acacia mearnsii, Acer sp., Quercus sp., Pinus spp., and Schinopsis spp. In this context, MT (commonly called as jurema-preta) is a native plant from the caatinga vegetation and its bark has a high amount of tannins [5-6].

In general, vegetable tannins have high reactivity [7-8], ability to unite proteins [9] and metals [10], as well as antifungal [11] and antioxidant [12] activities. These substances have a highly branched chemical structure [2, 13], which hinders their isolation, purification, and even their characterization. For this reason, they are usually sold as liquid or powdered extracts. Missio et al. [12] studied a powdered industrial tannin (IT) and reported that it is rich in condensed tannins (70-80%) and also have a minor portion of non-tannic materials, such as hydrocolloid gums, sugars, and small molecules (20-30%). Chemical modifications can be performed in condensed tannins through the incorporation of reactants, like hydrolysis and sulfonation reactions [2]. These reactions may increase the extraction yield and the overall quality of the tannin extract (including its solubility) in order to adjust these features of tannin-based extracts to each required use, like adhesives for wood products.

Currently, several bio-based adhesives have been developed in order to gradually replace synthetic ones designed for the timber industry. The use of renewable raw materials from plant sources for developing new materials or improving existing ones has increased significantly in recent years. These ecological solutions intend to replace conventional materials related to the oil production chain and other toxic materials with technical, environmental and economic advantages. Although suitable bonding qualities were already attributed to these green compounds for gluing wood surfaces, there are numerous physical and chemical influential factors related to pressing conditions, adhesive, wood, and their interfaces [14-16].

The use of condensable tannins (extracted from the MT bark) as raw materials to obtain novel products and/or by-products may follow some concepts, like bioeconomy and integrated biorefinery systems. This means that the valuable chemical compounds belonging to biomasses must be extracted based on profitable pathways and the involved environmental issues must be taken into account from an economic perspective. In this paper, tannin-based extracts were obtained from MT bark using different solvents and their potential to produce wood adhesives were ascertained. Additionally, an industrial tannin was used as a positive control.

Material and methods

Raw materials
The vegetal sample came from Fazenda Experimental do Núcleo de Pesquisas do Semiárido (NUPEÁRIDO), which is belonging to Universidade Federal de Campina Grande (UFCG) and has the geographic coordinates of 07°05'10" S and 37°15’43" W. A random sampling of ten (shrubs and trees) MT were performed during the summer and these individuals were overturned. Subsequently, their barks were removed, mixed, and air-dried in the shade. Then, they were fragmented in a hammer mill (forage) coupled to a 150 mesh screen (opening of 1.00 mm). The homogenized material was then hermetically sealed using nylon bags.

The IT (Phenotan M®) consisted of a powder extraIT from Acacia mearnsii De Wild. Bark and was donated by TANAC S/A, which is located at Montenegro/Brazil. Detailed information on the constitution and the performed industrial extraction was reported in previous manuscripts [2, 12, 17]. Pine wood samples were obtained from a local market located at Patos/Brazil. Sodium hydroxide (NaOH) and sodium bisulfite (NaHSO₃), both of them in micro-pearls and analytical grade, as well as formaldehyde (CH₂O, 37 wt.% aqueous solution) and hydrochloric acid (HCl, 10 M aqueous solution) were purchased from Neon Comercial (Suzano/Brazil). All these chemicals were used as supplied.

### Production of the tannin-based extracts

For obtaining both tannin-based liquid (LE) and powdered (PTE) extracts, the moisture content (MC) of the bark (sample with 10 g) was determined according to the ASTM D6403 [18]. Three solvents were used, namely distilled water (5000 mL), 0.5% NaOH aqueous solution, and 0.5% NaHSO₃ aqueous solution. The aqueous solvent and the MT bark (air-dried) sample were mixed at a 10:1 weight ratio in all extractions. The extraction process was carried out into a vertical autoclave (a stainless steel cylindrical reservoir) at a constant temperature of 120 °C and a pressure of 0.9 MPa for 150 min. Four replicates (extractions) were performed for each solvent.

After the extractions, the LE was purified by sieving on a quantitative filter paper (grade 40: 8 μm) coupled to a Millipore system and a vacuum pump. The pH and temperature of the solutions and purified LE in were determined (triplicates) along with both extraction and purification steps. Soon after the filtration step, the purified LE (each repetition) was immediately reduced to a dry powder in an oven with forced air circulation adjusted at 70 ± 2 °C for 48 h. The mass was registered for determining the crude PTE content (Equation 1).
\[ E_{Yc} = \left( \frac{M_c}{M_p} \right) \times 100 \]  
(1)

Where: \( E_{Yc} \) is the crude powder extract content (in %), \( M_c \) is the dry mass of crude powder extract (in g), and \( M_p \) is the dry mass of raw material (in g).

The crude PTE was processed in a Wiley mill coupled to a 60 mesh screen (< 0.25 mm). The refined extracts were packed in opaque plastic bottles and hermetically sealed. The refined PTE content was calculated according to Equation 2.

\[ E_{Yr} = \left( \frac{M_r}{M_p} \right) \times 100 \]  
(2)

Where: \( E_{Yr} \) is the refined powder extract content (in %), \( M_r \) is the dry mass of refined powder extract (in g), and \( M_p \) is the dry mass of raw material (in g).

**Characterization of the powdered tannin-based extracts (PTE) and CT**

Attenuated total reflectance with Fourier transform infrared spectroscopy (ATR/FTIR) was used to analyse the refined PTE and CT. For that, a Nexus 470 (Thermo Nicolet brand) infrared spectrophotometer was adjusted to total absorbance. For each sample (1.0 mg), 32 scans were performed at the 4000 to 600 cm\(^{-1}\) spectral range with an applied resolution of 4.0 cm\(^{-1}\). The obtained spectra were normalized and their baseline were corrected.

For preparing analytical solutions, 6.0 g of each tannin sample was gradually mixed with 1000 mL of distilled water at a constant temperature of 95 °C. Then, the material was naturally cooled and stored according to the D3790, D4904, and D4905 standards [19-21]. Total solids content (TS) was determined according to D4902 and D4903 [22-23]. The MC was calculated by the difference between the total mass (100%) and the TS. The MC influences the other parameters (soluble and insoluble solids, condensed tannins, and non-tannins) and, because of that, these chemical parameters of the PTE were adjusted to its MC using Equation 3.

\[ M_{0\%} = M_s \times \left[ 1 - \left( \frac{MC}{100} \right) \right] \]  
(3)

Where: \( M_{0\%} \) is the dry mass (in g), \( M_s \) is the air-dry mass (in g), and \( MC \) is the moisture content (in %).
A 100 mL aliquot of the analytical solution was filtered in a quantitative filter paper (grade 40: 8 μm with medium speed and retention). Thus, the soluble solids content (SS) was determined by the gravimetric method, based on the dry mass (filtrate liquid) measured after a drying process performed in an oven with forced air circulation (100 ± 4 °C). The insoluble solids content (IS) was the difference between the TS and the SS according to the NBR 14362 and D6402 [24-25]. Condensed tannins content (CT) was measured based on the reactivity of the extract (aliquot with 0.4% pure condensed tannins) with formaldehyde using Equation 4, as reported in the literature [26-28]. For this, an amount of 100 mL of filtered aliquot was subjected to a Stiasny reaction by adding 2 mL of HCl and 8 mL of CH₂O. This mixture was kept under reflux for 30 min and stirring every 5 min. The generated precipitate was filtered on quantitative filter paper (40: 8 μm grade with medium speed and retention) and was then washed using distilled water and dried at 100 ± 4 °C in an oven with forced air circulation adjusted.

The non-tannins content (NT) was obtained by the difference between the SS and the IT (Equation 5). The condensed tannins content in the aliquot of the analytical solution was determined using Equation 6. When any repetition did not meet a concentration of 0.4 ± 0.025% (using 6.0 g), an adequate amount of air-dried powder extract was used as a replacement (Equation 7).

\[
CT = \left( \frac{M_{pt}}{M_{0\%}} \right) \times 100 \quad (4)
\]

\[
NT = SS - CT \quad (5)
\]

\[
Ct = \left[ \frac{(Ma \times 100)}{A} \right] \quad (6)
\]

\[
Me_c = \left[ \frac{(Ma \times 0.4)}{Ct} \right] \quad (7)
\]

Where: CT is the condensed tannins content (in %), Mpt is the dry mass of the precipitate extrapolated to the total volume of the beneficiary's extract solution (in g), M₀% is the dry mass of the powder extract used in the preparation of the analytical solution (in g), NT is the non-tannins content (in %), SS is the soluble solids content (in %), Ct is the concentration of pure condensed tannins in the aliquot (in %), Ma is the dry mass of the precipitated condensed tannins (in g), A is the aliquot volume (in mL), Me_c is the appropriate mass of the powder extract to a concentration (in g), and Ma is the air-dried mass of the powder extract used in the preparation of the analytical solution (in g).
Characterization of the tannin-based adhesives

Tannin-based adhesives were prepared using both the refined PTE and IT according to the formulations displayed in Table 1. The experiment was carried out in triplicates for each adhesive formulation. All the adhesives were prepared as indicated by each supplier, except the MT + NaOH (refined PTE) since its concentration hinder adequate hydration of the extract. The powdered extract was mixed with distilled water at a constant 60 °C and was then kept at room temperature for 24 h until reaching its equilibrium moisture content. Wheat flour and CH₂O were applied as a glue extender and a catalyst, respectively. The flour had a particle size smaller than 0.25 mm (60 mesh).

Where: a Moisture content ~ 6-8%; b Based on the mass of the resin mix; c Percentage in relation to the mass of base agent (powdered tannin).

The solid content (SC) of the tannin-based adhesives was determined by evaporation of the moisture in a 1.0 g sample oven-dried with forced air circulation adjusted at 100 ± 4 °C. The SC was calculated according to Equation 8. Viscosity was determined using an EEQ-9031 analog rotational viscometer (Brookfield-LV type) [29], with a rotor spindle no. 3 and a rotation speed suitable to each adhesive. The pH at room temperature (25 ± 2 °C) was determined before and after the addition of CH₂O using a LUCA-210 digital benchtop pH meter [30]. The gel time was measured based on that method reported by [31-32] after the incorporation of the CH₂O (in a proportion of 20% of the mass of SC).

\[ SC = \left( \frac{M_d}{M_a} \right) \times 100 \] (8)
Where: SC is the solid content of adhesive (in %), Md is the dry mass of adhesive sample (in g), and Ma is the mass of adhesive sample (in g).

**Bonding of the wood joints and their evaluation**

The used pine wood boards presented basic density, apparent density, and moisture content of 0.37 g cm\(^{-3}\), 0.43 g cm\(^{-3}\), and 9.53%, respectively. This raw material was transformed into prismatic specimens with the dimensions of 1.90 × 5.10 × 5.40 cm\(^3\) (tangential × radial × longitudinal). To prepare the wood surfaces for bonding, they were sanded in the longitudinal direction using an electric circular sander (sandpaper no. 120). A weight of 300 g·m\(^{-2}\) of each tannin-based adhesive was applied on tangential plane and spread with a glass trowel. Then, a manual assembly was carried out for 15 min, which was followed by cold pre-pressing for 30 min, and then a hot pressing at 120 °C and 0.5 MPa for 60 min. Finally, the samples were post-cured at room temperature for 15 days.

The glue line of the pine wood joints was analysed by scanning electron microscopy (SEM) using a Tescan (VEGA-3) equipment. The radial plane was coated with gold particles to ensure a suitable electrical conductivity and the SEM images were acquired under an accelerating voltage of 10 kV. The glue line was evaluated for shear strength following the ASTM D905 [33]. For that, a compressive load was applied on the transverse plane (i.e. perpendicularly to the glued plane, which became a shear plane). All mechanical tests were carried out using a Shimadzu universal testing machine with 100 kN capacity (Figure 1a). Afterwards, the glued plane was visually evaluated and the percentage of failed wood was determined according to ASTM D5266 [34]. Based on the total shear plane, this indicates the percentage of cohesive failure in the wood. For that, it was used a transparent checkered grid with one hundred equal parts and the dimensions of 4.40 × 5.10 cm\(^2\) (length × width) (Figure 1b). Also, the MC of the samples was determined by gravimetric analyses soon after the mechanical tests.
Fig. 1 Photographs of the shear test setup (a) and the glued plane of a failed pine wood sample (b).

Statistical analyses

Data normality and homoscedasticity of variances were verified using Shapiro-Wilk tests and Bartlett tests, respectively. A completely randomized design was applied. The data were subjected to analysis of variance (ANOVA) followed by Fisher-Snedecor tests. When the null hypothesis was rejected, a comparison of means was performed using Fisher tests. A significance level of 5% was adjusted for all tests.

Results and discussion

Evaluation of the extraction process

The water (used in all treatments) presented a slightly acidic pH, as shown in Table 2. The addition of the MT bark induced strong acidification in the aqueous solution due to the leaching of some organic extractives, like condensed tannins (for instance, proanthocyanidins and saponins), sugars (c.a. glucose, starch, terpenoids, and alkaloids) [35-38], and minerals (a minor amount). This occurs due to the high polarity of the water (used as a solvent), which causes progressive solubilisation of some hydrophilic compounds from the MT bark. Among the extractives belonging to tree barks, some water-soluble tannins (polyphenolic molecules) and weak acids release H+ ions in the aqueous solution, leading to the deprotonation of hydroxyls. Similar results were obtained with the addition of bark and NaHSO₃, which induced a slight increase in the pH of the purified LE. The low pH of the sulphated LE can be attributed to the acid character of NaHSO₃, which generally ranges from 4.0 to 4.7.

*After 15 min. Where: numerals refer to averages ± standard deviations.

The incorporation of bark and NaOH led to increases in the pH of the solution (normally strongly alkaline) due to the dissociation of hydroxyl ions (OH⁻). The solution generated strong odour gases when heated and the purified LE demonstrated a decrease in pH after the extraction process. The NaOH is a strong base prone to react in an aqueous medium through an exothermic chemical process [39], which promotes the attack of free radicals present in the vegetable raw material (c.a. bark) and leads to the removal and conversion of soluble substances belonging to the extract.

**Powder extract yields**

The air-dried particles of the MT bark showed MC and dry mass of 11.25 ± 0.44% and 443.79 g, respectively. Besides, there were no significant differences between groups. The yields of PTE was the first parameter to determine the extractive content belonging to the bark, which indicates the efficiency and productivity of the extractions. Regarding the crude powder extract content (EYc), the addition of MT + NaOH or MT + NaHSO₃ favoured a significant increase in the removal of extractives from the raw material. However, the former extracting agent promoted a higher percentage of extracted solids. Regarding the refined powder extract content (EYr), only the treatment with the addition of the latter extracting agent, significantly favoured the conversion into powder during beneficiation, as shown in Figure 2.
Fig. 2 Crude (EYc) and refined (EYr) PTE contents and side view of them. Averages (± standard deviations) followed by a same letter, in a same column, do not differ statistically from each other according to the Fisher test.

Based on these yields, the additions of the extracting agents (through hydrolysis and sulfitation) promoted significant increases in the extraction of solid tannin fractions from the MT bark. Some previous studies also found similar results using other extracting agents [2, 13, 40-42]. In the present study, the EYc values can be mainly attributed to the use of basic hydrolysis (NaOH) and sulfitation (NaHSO₃).

Regarding the composition of the extracts from the MT bark, several phenolic (like tannins) and non-phenolic substances (such as carbohydrates, esters, and insoluble inorganic compounds) were detected [6]. According to the literature [13], high purity tannins can be extracted using high levels of pressure and temperature, which leads to greater solubility of compounds, as well as decreased viscosity and improved movement of the solvents. However, an over-oxidation of the phenolic compounds may occur if the extraction takes a long time, which negatively affects the final extraction yield and its quality.

Regarding the MT + NaOH, there was a little transformation of the crude extract and, thus, significant loss (about 24%) during its processing, which was mainly due to the extraction and formation of more rigid components. This indicates that this solid phase is not easily fragmented into particle sizes less than 60 mesh (0.250 mm). In addition, the grinding of the crude powder extract probably affected the EYr due to a large amount of solid material being superimposed on the internal sieve of the rotation drum, consequently impairing the passage to the collection reservoir. This probably hindered the contact between the rotating rods from the mill and the particles from the powder.
This wood is known due to its high calorific value. In this region, there is a density of 65 trees per ha [43] and these thousands of cubic meters of logs are often burned for energy generation, which encompasses both firewood and charcoal consumed every year by residences, commercial establishments, and industrial plants. Lopes et al. [5] studied MT trees from Northeastern Brazil with a mean basal diameter of 11.4 cm and reported a mean dried mass of bark of 3.7-4.0 kg per tree. Therefore, the bark has a non-significant significant influence in the calorific power of the overall tree, even due to its known high content of impurities. In this context, it seems clear that the MT bark should be considered for noble applications, which may be achieved following biorefinery concepts.

Analysis of powdered tannin-based extracts (PTE)

FTIR spectra indicate the chemical structure of the different PTE and IT (Figure 3). According to Tondi [44], the 1800-600 cm\(^{-1}\) range is the most important region for tannins. In general, if compared to each other, the powder extracts have a similar molecular chemical structure since these differences are only related to the intensities of the existing bands, as well as minor displacements in some bands located at the 1630-650 cm\(^{-1}\) range. Briefly, the bands at 1800-1650 cm\(^{-1}\), 1650-1400 cm\(^{-1}\), 1400-1100 cm\(^{-1}\), and 1100-600 cm\(^{-1}\) refers to C=O stretching, C=C stretching in aromatic rings from phenolic compounds, C–O elongation in aromatic phenolics, and C–H elongation in aromatic compounds [44].
Fig. 3 FTIR spectra of the powdered tannin-based extracts.

In comparisons between the tannin-based extracts, the MT + NaOH showed the highest TS and the lowest MC (Table 3). The higher MC presented by the IT may be due to its higher hygroscopicity ascribed to its smaller particle size (< 100 mesh, 0.15 mm) when compared to the other tannins (< 60 mesh). This smaller particle diameter may lead to a greater surface area and, consequently, this tannin probably became prone to form chemical bonds with the humidity from the environment. These features also lead to a lower amount of solid powder extract.

The inclusion of extracting agents in the extraction process provided significant increases in the overall solubility of the PTE extracted from the MT bark. These results are comparable to those obtained for the CT. The use of the extracting agent (NaOH and NaHSO₃) also yielded an increase in SS from PTE and a decrease in the IS extracted from the MT bark.

In this study, only the properties obtained for the MT + NaOH PTE meet those parameters proposed by the IS6199-1971 [45]. This standard procedure regards a powdered black wattle extract and indicates that MC, IS, and tannic SS shall be of at least 6.77%, 1.22%, and 67.29%, respectively. Compared to the unmodified MT, the MT + NaOH showed a significant increase in CT and a decrease in NT, which yielded improvements in the PTE extracted under neat water. The use of MT + NaHSO₃ also resulted in greater CT if compared to the
unmodified MT, although the NT remained similar in this case. These results are different from those reported in a previous study on MT bark and some extractions done under hot water [46]. These divergences can be explained by some differences in extracting procedures, as well as differences in the used raw materials (like particle size of and extraction mechanism).

Where: Averages (± standard deviations) followed by a same letter, in a same column, do not differ statistically from each other according to the Fisher test. TS = Total solids; MC = Moisture Content; SS = soluble solids; IS = insoluble solids; CT = Condensed tannin; NT = non-tannins.

For the PTE, high values of both SS and CT are desired. In this sense, the use of MT + NaOH and MT + NaHSO₃ yielded higher values of these parameters. Low values of IS and NT are surely desired. However, with sulfitation, the same behaviour occurred for the CT and without the influence reducing of NT compounds. It is well known that sulfitation promotes the opening of heterocyclic rings of tannins and introduce sulfonic groups, which also lead to a reduction in the viscosity and increases in both extraction yield and solubilisation of tannins [2, 26]. The alkaline hydrolysis process promotes rearrangement of the tannins through the rupture of the
interflavonoid bond (C4-C8) and the opening of the heterocyclic ring connected to the ring of the flavonoid unit, which induce an increase in the solubility of the tannins, especially CT [2].

Properties of the tannin-based adhesives

The SC of the MT + NaOH-based adhesive was lower than the others (Figure 4a). This adhesive was formulated with a lower concentration of the base agent in the PTE and a greater amount of solvent (distilled water), which explains the lowest SC and the highest viscosity attributed to this adhesive. In this study, the modification at the time of hydration and solubilization of the PTE was performed to avoid reactivations of the solid compounds. When carried out in very alkaline conditions (like in the present study), the extraction of tannins produces high viscosity adhesives, which can hinder their subsequent use [47]. The reduction in viscosity is a common characteristic of the sulfitation of the LE and PTE, as it favours the breakdown of chemical bonds from the extract and, thus, leads to an increase in the viscosity of the adhesives. In addition, this may promote increases in both pH and gel time, which explains these results displayed in Figure 4b.

Fig. 4 Averages and standard deviations for the solid contents and viscosity (a) and potential hydrogens with (pHc) and without (pHa) catalyst and gel time (b) for the tannin-based adhesives.

Adhesives with viscosity means greater than 1500 cP are not able to be applied via microparticles [48], and those above 6000 cP are not suitable to be applied on solid woods [49]. However, they can be applied directly and manually on the wood using spatulas or rollers. The higher viscosity of adhesives can yield the formation of a glue line thicker than that ideal due to an uneven distribution on the wood surface and inadequate wetting of the adhesive [16].
The MT + NaOH adhesive presented a basic pH, whereas the others have acidic levels. The pH of the adhesives must not exceed the 2.5-11.0 range [50], although the pH of the wood is also important since affects that time required for total curing and hardening of the glue. There were decreases in the pH of all the adhesives due to the addition of the catalyst (CH₂O). After mixing, chemical reactions started in the adhesive solution (with the release of H⁺ ions), which ended above 90 °C and caused a phase change to form the adhesive gel (by a complete cure of the resin). The extracting agents significantly increased the gel time (phase change), which is desired since adhesives with a very short gel time hinder an adequate spreading over the wood surface since a rapid polymerization may occur leading to decreases in the glue line strength.

The condensation of tannins due to the presence of formaldehyde under heating (95-100 °C) is strongly influenced by the pH of the medium, as there is an increase in the reaction speed if there is a decrease in the pH [51]. According to Tondi [44], an amount of about 4% of this catalyst is enough to promote the polymerization of tannin-based resins.

Azevêdo et al. [49] produced sulfited (Na₂SO₃) tannin adhesives extracted from the MT bark cut in the dry period (August-December) and reported the following parameters: pH values from 5.69 to 5.76, SC from 46.8 to 46.9% and viscosity from 2067 to 10000 cP, which are similar to the present study. Some minor differences in a comparison with the present study are probably associated with the acid sulfitation process after extracting the bark, which was not done in the present study. The IT resin (Phenotan M®) extracted from the black wattle bark is commercialized with a MC of 5-8%, a viscosity (at 25 °C) from 1000 to 1600 Cp, and a pH ranging from 4.0 to 5.0 [17]. The IT adhesive showed the lowest viscosity among those analysed here, as well as the greatest fluidity and, consequently, this adhesive was easily spread on the wood surface.

**Bonding performance of the tannin-based adhesives**

The different tannin-based adhesives used for bonding the wood joints promoted uniform glue lines as shown in Figure 5. All the MT adhesives promoted thick glue lines in the union between the wood surfaces, which is mainly due to their high viscosity, as aforementioned. In general, this may impair the adhesive-wood connection but may positively contribute to the union in the internal layers of the adhesive. This fact may limit its full capacity of undergoing external loads on a large scale, such as shear forces.
Fig. 5 Side view of the glue lines promoted by the bonding with the tannin-based adhesives. Where a, b, c, and d refer to MT, MT + NaOH, MT + NaHSO₃, and Phenotan M® (IT), respectively.

The shear strengths of the MT and MT + NaOH adhesives overcame that of the IT (Table 4). The same behaviour was demonstrated in the evaluation of the percentage of wood failure on the shear plane. According to a previous study [52], the bonding of wood joints with tannin-based adhesives often do not reach a minimum safety rate due to the low viscosity of the tannin resins and, consequently, high leakage lines are normally formed. These results are contrasting with those of the present study, which is probably due to the viscosity of the adhesives and their chemical composition.

Where: MC is moisture content of the glued wood sample (dry basis). Averages (± standard deviations) followed by the same letter, in a same column, do not differ statistically from each other according to the Fisher test.

According to the NBR 7190 [53], the shear strength parallel to the fibres in softwoods varies from 4 MPa to 6 MPa for a 0.4-0.5 g cm$^{-3}$ basic density range. On the other hand, according to the ASTM D5751 [54], the shear strength mean for glued joints must reach at least 60% of shear strength belonging to the respective solid wood. Based on these different standards, those shear strengths displayed in Table 4 should range between 2.4 and 3.6 MPa.

The ASTM D2559 [55] also indicates that, for a satisfactory bonding with structural adhesives (designed for outdoor uses), a minimum average value of 75% of wood failure must be reached. For dried laminated joints and other non-structural joints, the minimum percentage of failed wood is 60%, which is visualized on the shear plane [54]. In this evaluation, the higher the percentage of wood failure, the higher the bonding quality, which is mainly associated with characteristics of both adhesive-adhesive and adhesive-wood interfaces. None of the adhesives reached these levels proposed in ASTM D2259. This may be related to the high viscosity of the different adhesives from MT bark. This factor probably impaired the spreading and wetting of the glue on the wood surfaces, thus, negatively affecting the cohesion between adhesive molecules and the overall adhesive-wood interface. Moreover, although the IT resin is commonly used for the manufacture of plywood and other structural wood parts [17], in this study, its use was adapted for lateral bonding of wood joints, which probably impaired its mechanical performance.

The phenomenon of connections at the adhesive-wood and adhesive-adhesive interfaces depends on several simultaneous factors, such as anatomy, physics and chemistry of the wood, physicochemical properties of the adhesive, and the bonding process. In further studies, a decrease in the viscosity of the adhesive may favour an improvement of the bonding quality. This would provide an improved penetration of the wood and thus increase in both the shear strength of the glue line and the percentage of wood failure on the shear plane.

Conclusions

Some valuable compounds from the *M. tenuiflora* bark have been wasted since this vegetable is
traditionally underutilized. By using a biorefinery concept, integrated and sustainable processing applied to this biomass may yield marketable chemicals, like a wood adhesive. In the present study, aqueous solutions containing 0.5% of NaOH and 0.5% of NaHSO$_3$ were successfully used as solvents to extract tannin-based compounds. Then, tannin-based adhesives were produced and yielded glue wood joints with promise mechanical performances, although the tested glue lines did not yield wood joints able to meet those parameters proposed in known standards. Nevertheless, the novel tannin-based adhesives showed better performances if compared to a commercial structural adhesive (IT). Further studies are strongly encouraged and may address different pressing conditions and the influence of the adhesive viscosity.

List of abbreviations
- MT: Mimosa tenuiflora; NTFPs: non-timber forest products; IT: industrial tannin; PTE: tannin-based powdered extract; LE: tannin-based liquid extract; MC: moisture content; TS: Total solids content; SS: soluble solids content; IS: insoluble solids content; CT: condensed tannins content; SC: solid content; EYc: crude powder extract content; EYr: refined powder extract content.

Availability of data and materials
All relevant data is presented in the manuscript, and additional information can be made available on request if necessary.

Competing interests
The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Funding
No funding has been provided for the research associated with this article.

Authors’ contributions
PJGL, WAMS, PNMN, and IAB developed the experiments and analysed the results. PJGL, RAD, and ALM proposed experimental solutions, validated the initial objectives of the project, and wrote the original draft. LC, RRM, and DAG were responsible for the funding acquisition. RAD helped for reviewing, editing and correcting both spelling and grammar errors.

Acknowledgments
The authors would like to thank CNPq and CAPES for supporting this work.
