Abstract

Background Patients with primary ovarian insufficiency (POI) occasionally present with follicle growth; however, it is difficult to predict exactly which cycles will show follicle growth. Serum anti-Müllerian hormone (AMH), a useful marker for ovarian reserve, is produced in early-stage follicles. Therefore, AMH levels should reflect the presence of small follicles, which are difficult to detect using ultrasonography, and may be useful as a marker for predicting follicle growth in patients with POI. **Methods** Using an ultrasensitive enzyme-linked immunosorbent assay (ELISA) kit, we found very low serum AMH levels in patients with POI. We assessed the follicle growth of each patient during each cycle to clarify the usefulness of measuring serum AMH levels for predicting follicle growth in patients with POI under hormone replacement therapy (HRT). **Results** A total of 91 cycles of 19 patients with POI were analyzed in this study. Five patients presented with positive serum AMH levels during the observational periods, and all five experienced follicle growth. Only two of the 14 patients with negative serum AMH levels had follicle growth. Serum AMH and follicle-stimulating hormone (FSH) levels in cycles with follicle growth were significantly higher than in cycles without follicle growth. The median serum AMH level (2.77 pg/mL; 25 th , 75 th percentiles: 0.0, 9.64) in cycles with follicle growth was lower than the lower limit of detection of conventional AMH ELISA kits. The positive predictive value of positive serum AMH levels for follicle growth was higher than that of FSH (< 10 mIU/mL). **Conclusions** Measurement of very low levels of serum AMH using picoAMH assays is useful for prediction of follicle growth in patients with POI under HRT conditions.

Background

Primary ovarian insufficiency (POI) is defined as the development of hypergonadotropic hypogonadism before the age of 40 years (1)(2). POI is one of the causes of intractable infertility. Due to the current trend of women delaying having their first child until later in life, the number of patients with POI who desire children is increasing. Some patients with POI have follicle growth occasionally (3), although it is difficult to predict which cycles will show follicle growth. Currently, serum follicle-stimulating hormone (FSH) or estradiol (E2) levels are measured in the clinical setting to help predict follicle growth in patients with POI. Serum E2 levels were reported to be a useful predictive factor for ovarian function in patients with POI (4); however, an elevation of serum E2 levels is a result of follicle growth, and therefore, follicles are already growing in these conditions. Likewise, serum FSH levels are affected by hormonal therapy, and consequently, some cycles with low serum FSH levels did not show follicle growth even with ovarian stimulation due to prior human gonadotropin injections (5)(6).

Thus, markers with higher predictive value are required even in these conditions, in order to avoid ineffective ovarian stimulations which result in not only economic, but also physical and psychosocial, burdens for the patients.

Among several markers for ovarian reserve, the serum level of anti-Müllerian hormone (AMH), which is produced by the granulosa cells of early-stage follicles, is considered to be one of the most informative

markers for ovarian reserve (7)(8)(9). Measurement of AMH levels in the clinical setting has thus been used extensively in, for example, the prediction of ovarian response to controlled ovarian stimulation by gonadotropins, optimization of protocols in assisted reproductive technology, and assessment of ovarian toxicity in medical and surgical conditions (9)(10)(11)(12). In recent years, a new AMH ultrasensitive enzyme-linked immunosorbent assay (ELISA) kit, the picoAMH ELISA (MenoCheck picoAMH, Ansh Labs, Webster, TX USA) for the detection of very low serum AMH levels, has become available. The lower limit of detection (LoD) of the picoAMH ELISA is 3 pg/mL. This is significantly lower than that of the Gen II AMH ELISA (Beckman Coulter Inc., Brea, CA USA), one of the most prevalent AMH assay kits, which has a LoD of 80 pg/mL. We reported that measuring very low serum AMH, which is not detected by conventional ELISA kits, in patients with POI was useful for predicting true ovarian reserve (13).

In the current study, we investigated the usefulness of measuring very low levels of serum AMH using an ultrasensitive AMH assay kit, picoAMH, as the marker for follicle growth of a cycle in patients with POI under HRT conditions.

Methods

Patients

Patients with POI who underwent cyclic hormonal therapy between April 2013 and March 2019 were recruited for the study. Patients with POI are defined as those under 40 years of age who exhibit serum FSH levels > 40 mIU/mL on at least two different tests, and present with amenorrhea for more than three months in the absence of hormonal therapy. The cyclic hormonal therapies administered included conjugated equine estrogen (Premarin®; Pfizer Inc., New York, NY USA), 2 tablets/day for 10 days followed by an estrogen (0.05 mg ethinylestradiol) and progestin (0.5 mg norgestrel) combination (Planovar®; Takeda Pharmaceutical Company Limited, Chuo-ku, Tokyo, Japan), 1 tablet/day for 11 days, or alternatively Premarin® 2 tablets/day for 21 days with chlormadinone acetate (Lutoral®; Fuji Pharma Co. Ltd., Chiyoda-ku, Tokyo, Japan), 2 tablets/day, for the last 11 days. Following a 21-day treatment with a given cyclic hormonal therapy protocol, patients were subjected to a seven-day withdrawal period before the next cyclic hormonal therapy was started. If serum E2 levels exceeded 30 pg/mL, or serum FSH levels dropped to < 15 mIU/mL, during the withdrawal period, the next cyclic hormonal therapy was suspended, and the follicles were monitored once or twice a week by ultrasonography. Follicle growth was defined as the presence of follicles with a mean diameter > 16 mm. In some cases, human menopausal gonadotropins were administered for controlled ovarian stimulation. This study was approved by the ethical committee of Nagoya University Graduate School of Medicine, and informed consent was obtained from all patients.

Hormonal measurements

Blood samples were obtained during the drug withdrawal period of each patient. Serum was isolated using a centrifuge and separated from the whole blood samples, transferred to sterile polypropylene tubes, and stored at -80°C until the assays were performed. The serum picoAMH concentrations were

measured using the picoAMH ELISA kit, according to the manufacturer's instructions (14)(15) by the same operator. The dynamic range of the standard curve of the picoAMH was from 3.0 to 746 pg/mL, and the LoD and limit of quantitation (LoQ) were 1.2 pg/mL and 3.9 pg/mL, respectively, in accordance with the manufacturer's specifications. In this study, 0.00 pg/mL measured with the picoAMH was defined as an undetectable (negative) AMH. The absorbance measurements were performed using a microplate reader (ELx808™ Absorbance Microplate Reader; BioTek Instruments, Inc., Winooski, VT USA). Concentrations of serum antithyroperoxidase antibody (TPOAb), antithyroglobulin antibody (TgAb), E2, and FSH were measured using enzyme-linked immunosorbent assay kits (Elecsys Anti-Tg, Anti-TPO; Roche Diagnostics, Rotkreuz, Switzerland; ARCHITECT® Estradiol, ARCHITECT® FSH; Abbott Laboratories, Abbott Park, IL USA). Serum TPOAb levels > 16 IU/mL and TgAb levels > 28 IU/mL were considered positive.

Statistical analyses

The data were analyzed using the Prism software (Prism 8; GraphPad Software, San Diego, CA USA), and EZR software (Version 1.40; Saitama Medical Center, Jichi Medical University, Saitama, Japan), the latter of which is a graphical user interface for R (The R Foundation for Statistical Computing, Vienna, Austria). More precisely, EZR is a modified version of R Commander designed to add statistical functions that are frequently used in biostatistics (16). Mann–Whitney *U* tests were used to compare patient characteristics, including hormone levels, while Fisher's exact tests were applied to compare the proportions of groups. A p-value of < 0.05 was considered to indicate the level of statistical significance.

Results

A total of 91 cycles of 19 patients with POI were analyzed in this study. Out of the total of 19 patients, four had histories of chemotherapy, three had a documented chromosomal abnormality, and 12 patients lacked a definitive cause for the POI. Out of these 12 patients, seven were positive for thyroid autoantibodies (TPOAb and/or TgAb). Table 1 shows the patient characteristics categorized by positive or negative serum AMH measured using the picoAMH kits. The median age of onset of POI did not differ between the negative and positive AMH groups. All of the patients with one or more AMH-positive cycles experienced follicle growth during the observation periods. In contrast, out of the group of patients who were AMH-negative, only 14.3% experienced follicle growth (Table 1).

Table 1. Comparison According to Serum AMH in patients with POI.

Variable	Overall (n = 19)	AMH-negative (n = 14)	AMH-positive (n = 5)	p-value b
Age at onset of POI (years)	17.0 (15.0, 23.0)	16.0 (14.0, 20.0)	22.0 (17.0, 27.0)	0.876 ^c
Age at first observation period (years)	25.2 (23.4, 30.8)	24.8 (20.7, 31.2)	27.6 (24.7, 33.4)	0.3913 ^c
Serum FSH ^a (mIU/mL)	46.4 (22.7, 70.5)	46.4 (33.1, 75.3)	66.2 (13.2, 78.5)	0.9644 ^c

^d Fisher's exact test

For the purpose of evaluating AMH as a predictive factor for follicle growth of the cycle, we analyzed the serum levels of AMH and FSH and the follicle growth of each cycle. Of the total 91 cycles, 14 were positive for AMH, and 14 cycles presented with follicle growth. The serum FSH levels of the cycles with follicle growth were significantly lower, and the serum AMH levels significantly higher, than those in cycles without follicle growth (Figure 1). The median serum FSH and AMH levels of cycles with follicle growth were 15.44 mIU/mL (25th, 75th percentile: 5.03, 26.85) and 2.77 pg/mL (25th, 75th percentile: 0.0, 9.64), respectively. Out of the 14 AMH-positive cycles, nine presented with follicle growth, and five did not show follicle growth. However, of these five cycles, two were positive for AMH in the previous cycles. Serum FSH levels in the AMH-positive cycles were significantly lower than in the AMH-negative cycles (Table 2).

Table 2. Serum AMH and FSH and follicle growth in AMH-positive or negative cycles.

Variable	AMH-negative (n = 77)	AMH-positive (n = 14)	p-value
Serum FSH (mIU/mL)	33.0 (20.4–49.0)	10.0 (5.0–26.6)	0.0058 ^a
Serum AMH (pg/mL)	0.0 (0.0–0.0)	7.7 (4.6–22.3)	<0.0001 ^a
Follicle growth, n (%)	5 (6)	9 (64)	<0.0001 ^b

AMH, anti-Müllerian hormone; FSH, follicle-stimulating hormone

^b Fisher's exact test

The positive predictive value (PPV) and negative predictive value (NPV) of AMH-positive serum for follicle growth of the cycle were 0.643 and 0.935, respectively. At the same time, we assessed the usefulness of serum FSH levels in the prediction of follicle growth. When we set FSH levels < 10 mIU/mL as a predictor of follicle growth, the PPV of FSH was 0.250 and the NPV was 0.873. These results indicate that AMH-positive serum during the withdrawal period is superior to low levels of serum FSH as a predictor of follicle growth in the cycle.

Discussion

In this study, we demonstrated that detection of very low serum AMH levels in patients with POI can be used as a marker for predicting follicle growth of the current cycle. In patients with POI, it has been reported that the possibility of spontaneous ovulation is about 4% during a cycle (3); however, it is difficult to predict the exact cycle which will present with follicle growth. Gonadotropin therapy with exogenous estrogen is one of the most common strategies for the induction of follicle growth in patients with POI (17)(6)(4). It has been reported that ovulation only occurred in patients with lower serum FSH (< 15 IU/mL) after estrogen therapy (6), resulting in an ovulation rate of 32% with this therapy, higher than the spontaneous ovulation rate of patients with POI. However, 70% of the patients who underwent ovarian stimulation did not achieve ovulation.

In the current study, serum FSH levels in cycles with follicle growth were significantly lower than those in cycles without follicle growth. However, the PPV and NPV of serum FSH < 10 mIU/mL as a prediction marker for follicle growth were 0.25 and 0.837, respectively, resulting in 75% of the cycles with lower FSH levels not presenting with follicle growth. In contrast, the PPV and NPV of AMH-positive serum were 0.643 and 0.935, respectively, significantly higher than those of low levels of serum FSH (< 10 mIU/mL).

Moreover, the median serum AMH level of cycles with follicle growth was 2.77 pg/mL (25th, 75th percentile: 0.0, 9.64), an undetectable level using the Gen II AMH ELISA (LoD: 80 pg/mL) or automated

assay systems such as the Elecsys AMH (LoD: 10 pg/mL, Roche Diagnostics) and the Access AMH (LoD: 20 pg/mL, Beckman Coulter Inc.) (18)(15).

There were five cycles presenting with follicle growth which had AMH-negative serum. Of these five cycles, two were AMH-positive in the previous cycle. Additionally, patients who had positive AMH levels one or more times presented with follicle growth during the observational periods. These results indicate that the measurement of very low serum AMH levels was useful for predicting follicle growth in patients with POI.

We acknowledge that there were several limitations to this study. Firstly, the numbers of patients and cycles included in this study were small. However, the frequency of ovulation of the patients and the frequency of cycles were 3.7% and 1.5%, respectively, and these rates were similar to those reported in a previous study (3). Secondly, an automated assay system for picoAMH is not presently available, and consequently, it is difficult to get same-day results of picoAMH testing. Since serum AMH levels are not affected by hormonal status (19)(20), clinicians may measure AMH serum levels during hormonal therapy, or several days before the withdrawal periods, in order to predict follicle growth. Thirdly, the results of this study are limited to the prediction of follicle growth, and all seven patients who exhibited follicle growth in this study have failed to achieve pregnancy. Previous reports indicated that the median serum AMH level of patients with successful IVF was 837 (range: 141.6-2750) pg/mL (21), and live birth rate was significantly lower in women with $\text{AMH} \leq 0.1 \text{ ng/mL}$ (22). Consequently, it cannot be declared that detection of AMH by the picoAMH kit in POI patients raises the probability of successful IVF or pregnancy. Fourthly, donor oocytes are available for patients with POI in some countries. However, there are still difficulties regarding accessing oocyte donations in some countries. Moreover, *in vitro* fertilization (IVF) with donor oocytes has some issues, such as the high expense and concerns regarding genetics. In addition, some reports have suggested that patients with spontaneous POI have an increased risk of perinatal complications, such as pregnancy-induced hypertension and postpartum hemorrhage, when they become pregnant using IVF with oocyte donation (23)(24). Therefore, the availability and feasibility of IVF with autologous oocyte could be significant for patients with POI.

In 2018, the U.S. Food and Drug Administration permitted marketing of the picoAMH ELISA diagnostic test as an aid in the determination of a patient's menopausal status (25). In addition to predicting menopausal status, the picoAMH ELISA kits may have significance for patients with POI who desire to have children.

Conclusion

In conclusion, we demonstrated the usefulness of very low levels of serum AMH as a marker for follicle growth in patients with POI. Further studies with larger numbers of patients are expected to demonstrate the benefits of measuring picoAMH in patients with POI.

Abbreviations

POI: primary ovarian insufficiency

HRT: hormone replacement therapy

FSH: follicle-stimulating hormone

E2: estradiol

AMH: anti-Müllerian hormone

TPOAb: antithyroperoxidase antibody

TgAb: antithyroglobulin antibody

ELISA: enzyme-linked immunosorbent assay

PPV: positive predictive value

NPV: negative predictive value

IVF: *in vitro* fertilization

Declarations

Ethics approval and consent to participate

The study was approved by the ethical committee of Nagoya University Hospital (approval reference number 422), registered as a clinical trial (UMIN000029464) on April 4, 2018, and informed consent was obtained from all patients prior to enrollment. All procedures were performed according to the Declaration of Helsinki regarding human experimentation.

Consent for publication

Not applicable.

Availability of data and materials

The datasets analyzed during the current study are available from the corresponding author on reasonable request.

Competing interests

The authors declare no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Funding

The authors received no financial support for the research, authorship, and/or publication of this article.

Authors' contributions

YK performed the data analysis and the writing of the manuscript. SO analyzed and interpreted the data. Bayasula measured serum levels using the picoAMH assays. Data were collected and analyzed by TM, NN, and TN. Interpretation of the data was done by MG, TK, AI, and FK. All authors read and approved the final manuscript.
