Abstract

**Background**: Biallelic inactivation of *TP53* has been included in the definition of double-hit (DH) multiple myeloma (MM), which entails an ominous prognosis even when treated with the most innovative drugs. However, this condition, or even the presence of high-risk cytogenetic abnormalities, cannot accurately capture the 15-20% of the MM population with a median overall survival below 24 months. This prompted us to look for other MM patients who might have transcriptional characteristics similar to those with DH-*TP53*.

**Methods**: We analyzed RNA-seq, whole-genome and whole-exome sequencing data from 660 newly diagnosed MM (NDMM) patients from the MMRF (Multiple Myeloma Research Foundation) CoMMpass study to characterize the transcriptional signature of DH-*TP53* MM. This gene signature was used to build a score based on a Spearman correlation coefficient and a scaled GINI index. Two other gene expression series from GEO (GSE4581 and GSE136400) comprising a total of 850 patients were used as validation cohorts.

**Results**: We found 78 genes that were exclusively deregulated in DH-*TP53* patients. A score based on these genes identified a group of 50 patients who shared the same transcriptional profile (DH-*TP53*-like group) whose prognosis was particularly unfavorable (median overall survival [OS] < 2 years), despite not harboring the biallelic inactivation of *TP53*. Patients included in the DH-*TP53*-like group had significantly shorter OS and progression-free survival (PFS) than those without the DH-*TP53* gene expression profile (hazard ratio [HR] 4.07 [95% CI, 2.76-5.98], adjusted \( p < 0.001 \), and HR 3.44 [95% CI, 2.46-4.81], adjusted \( p < 0.001 \), respectively). The prognostic value of the DH-*TP53* score was externally validated using gene expression data obtained by microarray analysis. Furthermore, our DH-*TP53* score refined the traditional prognostic stratification of MM patients according to the cytogenetic abnormalities and International Staging System (ISS).

**Conclusions**: The expression signature of DH-*TP53* MM was shared by other MM patients without *TP53* biallelic inactivation (DH-*TP53*-like group). The DH-*TP53* score could be a useful tool for identifying ultra-high-risk MM patients without concomitant del(17p) and *TP53* mutations.

Background

Multiple myeloma (MM) is a B-cell neoplasm characterized by great genomic and molecular complexity that largely explains the variability observed during the clinical course and in treatment response [1]. Cytogenetic abnormalities remain the most relevant prognostic factors. Deletion of chromosome 17p [del (17p)], which contains the *TP53* locus, is present in 8–13% of newly diagnosed MM (NDMM) patients and is probably the cytogenetic alteration associated with the most unfavorable prognosis [2]. *TP53* mutations, which also have a negative impact on survival, are also uncommon, occurring in only 3–6% of NDMM patients [3, 4]. *TP53* mutations are more frequent in patients with del(17p) [5]. Biallelic
inactivation of TP53 observed when the two abnormalities are present together, has been included in the definition of double-hit (DH) MM. DH-TP53, although rarely seen, entails an ominous prognosis [6].

Moreover, p53 can be deregulated by other mechanisms different from changes in DNA gene sequence, such as epigenetic regulation or altered expression of its regulators, which eventually lead to p53 dysfunction. The functionality of the different pathways controlled by p53 could be inferred by the expression of their numerous target genes. In this regard, a signature based on three genes (PUMA, GADD45 and THBS1) has been described to be associated with TP53 status in MM [7]. Furthermore, a transcriptional signature of patients with biallelic inactivation of TP53 has recently been defined. Interestingly, some relevant pathways deregulated in this signature, such as those related to cell cycle control and MYC regulation were also altered in the expression signatures specific to biallelic events involving other tumor suppressor genes [8].

Compared with solid tumors, DH-TP53 in MM is much more infrequent. However, ultra-high-risk MM, defined as those patients with a median overall survival less than 24 months, represents 15–20% of the MM population [9]. Although other high-risk cytogenetic abnormalities may account for this adverse prognosis, these kind of cytogenetic alterations are not present in all patients with such an unfavorable outcome. This prompted us to define the transcriptional signature of DH-TP53 and to find out if it was present in other patients who did not have biallelic inactivation of TP53.

Methods

Patient cohorts.

Genomic and transcriptomic data of 660 NDMM patients from the Multiple Myeloma Research Fundation (MMRF) CoMMpass study (NTC014554897, https://research.themmrf.org/) were analyzed. Survival data were retrieved from the interim analysis 16 release. The characteristics of the population are described in Additional file 1: Table S1. In addition to the CoMMpass database, two other series of MM patients, which included data from gene expression profiling analyzed by Affymetrix Human Genome U133 Plus 2.0 microarray, were selected as validation cohorts. One of them contained 414 patients treated according to total therapy 2 (256 cases) and total therapy 3 (158 patients) studies (GSE4581), and the other comprised 436 NDMM patients (GSE136400: only the CD138-positive cell samples were used for the analysis) enrolled in the total therapy 3–5 studies.

Identification of DH-TP53 signature.

Information about IGH translocations [t(4;14), t(11;14) and t(14;16)] and copy number abnormalities [1q gain and del(17p)] were obtained from the whole-genome sequencing-based fluorescent in situ hybridization (Seq-FISH) data [10]. Non-synonymous TP53 mutations assessed by whole-exome sequencing were also included in the analysis. Based on these chromosomal and gene alterations, six groups and a normal FISH group were defined. RNA-seq gene expression in the six groups was compared
with the normal FISH group to generate the corresponding differentially expressed gene lists (false-
discovery rate (FDR) < 0.05). All contrasts were performed using the DESeq2 R package (version 1.30.1)
on HTSeq count data. Genes from the six lists were then gathered to derive a Venn diagram using the
ggplot2 R package (version 3.3.5), which allowed us to determine the exclusive DH-TP53 signature.

**Score generation.**

The DH-TP53 signature was used to build a score [11]. Briefly, we generated two gene expression
matrices normalizing RNA-seq data using the vst function of the DESeq2 package or the cpm function
from the limma package (version 3.46.0). We then calculated a Spearman correlation coefficient using
the psych package (version 2.1.6), and a scaled GINI index through a random forest approach using the
h2o R package (version 3.32.1.3) for both matrices to identify the genes that best discriminated between
DH-TP53 from normal FISH. The score was then calculated as the mean of the absolute values of these
four parameters multiplied by the sign of the correlation coefficient. All the genes for which the 95%
confidence interval of the score included zero were discarded. Finally, we applied the score for each gene
g and calculated the sum for each patient p using the following formula:

\[
DH-TP53 score_p = \sum_g \left( \text{Score}_g \times \log_2 \text{expression}_{gp} \right)
\]

The score values for each gene g are listed in Additional file 2: Table S1. We used the value of the first
quartile of the score in the DH-TP53 group as the cut-off to determine the DH-TP53-like group.

**Validation of DH-TP53 score.** To validate the performance of the DH-TP53 score, we processed data from
the aforementioned two GEO series [12]. Thus, raw data from the GSE136400 series [13] were background-
subtracted, quantile-normalized and log₂-transformed using the affy package (version 1.68.0) in R with a
custom reference for the Human Genome U133 Plus 2.0 array from BrainArray (Ensembl version 25.0.0)
[14]. As no raw data were available from GSE4581 [15], we used the previously pre-processed data from
the GEO website. We transformed the probeset identifiers from the Human Genome U133 plus 2.0 array to
Ensembl identifiers to match RNA-seq data, and duplicated genes were randomly removed. It should be
noted that this second approach is less precise than the BrainArray approach, as microarray probe
ambiguity is not taken into account [16]. The per-patient score was then calculated for the two validation
series using the gene weights obtained in the main CoMMpass cohort. Patient scores from these two
series were arranged in descending order and split into two groups, based on a moving window of 5% of
the patients, to enable the survival analysis to be carried out.
Statistical analysis.

Univariable survival analysis was performed in R through the survival (version 3.2-7), survminer (version 0.4.9) and ggplot2 packages using the Kaplan–Meier estimator, with progression-free survival (PFS) and overall survival (OS) as endpoints. The resulting survival curves were compared using the log-rank test. Multivariable Cox proportional-hazards models were fitted in R through the coxph function of the survival package. The multicollinearity among predictor variables was quantified using variance inflation factors with the car package (version 3.0–12). The proportional-hazards assumption of these models was evaluated through the evaluation of the Schoenfeld residuals in R. Forest plots for multivariable analysis were drawn using the forestmodel package (version 0.6.2). Group differences between categorical variables were assessed with the chi square and Fisher’s exact tests, depending on the number of patients included in each group; those for continuous variables were examined using the Mann–Whitney U and Kruskal–Wallis tests, depending on the number of contrasted groups. Post-hoc tests for chi-square and Fisher's exact tests were performed using the fifer package (version 1.1). The Benjamini–Hochberg method was applied to adjust the \( p \)-value (\( p \)) for multiple testing, as required. The threshold of significance for unadjusted and adjusted values of \( p \) was set to 0.05. These analyses were performed using IBM SPSS Statistics 26.0 and R (version 4.0.4) packages.

Results

Identification of transcriptional pattern associated with TP53 biallelic inactivation

The 660-patient cohort was divided into six groups based on their cytogenetic and TP53 mutation status: t(4;14), t(11;14), t(14;16), 1q gain, del(17p) and DH-TP53. Gene expression profiles of these groups were determined by contrasting their RNA-seq data against those of patients with normal FISH (considered as the cases with none of the aforementioned abnormalities). Differential expression analyses of the 23 patients harboring TP53 biallelic inactivation (DH-TP53 group) identified 78 genes (FDR < 0.05) after subtracting the gene expression signatures of the five other groups (Fig. 1). The interactions between the proteins encoded by the genes involved in the DH-TP53 signature were represented using a weighted functional association network in STRING [17] (Additional file 2: Figure S1).

Development of DH- TP53 score

All the 78 genes exclusively deregulated in the DH-TP53 group met the inclusion criteria to be part of the DH-TP53 score (Fig. 2A). Based on this, we assigned the patients with a score above the first quartile of the DH-TP53 group to a new subgroup named DH-TP53-like. This subgroup consisted of 50 out of 660 (7.5%) NDMM patients and did not harbor the combination of the del(17p) and TP53 mutation. The other 587 MM cases corresponded with those patients who did not present biallelic inactivation of TP53 or whose scores were less than the selected threshold (“other patients” group) (Fig. 2B).
Clinical and biological characteristics of the DH-TP53-like group

No statistically significant differences in age, gender and Eastern Cooperative Oncology Group (ECOG) performance status were found between the DH-TP53 and DH-TP53-like groups defined by the score, or between them and the other patients. On the contrary, we detected higher levels of leucocytes, creatinine, beta-2-microglobulin, C-reactive protein and lactate dehydrogenase in the DH-TP53-like group than in the “other patients” group ($p < 0.05$, Additional file 1: Table S1).

Considering the most frequent cytogenetic abnormalities observed in MM, we found that t(14;16) was present in $12\%$ (6/50) of the DH-TP53-like patients compared with $3\%$ (20/587) of cases included in the “other patients” group (post-hoc adjusted $p = 0.035$). 1q gain was significantly more frequent in the DH-TP53-like group than in the other patients in the population, including those of the DH-TP53 group ($p = 0.001$). It is noteworthy that no statistically significant differences in the proportion of patients with del(17p) were observed between the DH-TP53-like and the “other patients” groups. The other cytogenetic abnormalities were equally distributed across the DH-TP53, the DH-TP53-like and the “other patients” groups (Fig. 3A; Additional file 1: Table S1).

We next analyzed the distribution of the most prevalent mutated genes across the three groups. None of the DH-TP53-like patients had any TP53 non-synonymous mutation, although $4\%$ (2/50) of them harbored other types of TP53 mutations. Conversely, the DH-TP53-like group was enriched for MAX mutations relative to the “other patients” group (post-hoc adjusted $p = 0.028$). We also noticed that none of the DH-TP53 patients had mutations of the NRAS gene (Fig. 3B).

Prognostic value of DH-TP53 score

DH-TP53 originated by the combination of the del(17p) and TP53 mutations had a significantly negative impact on survival (Fig. 4). On the other hand, the DH-TP53-like group defined by the score had a significantly shorter OS (hazard ratio [HR] 4.07 [95% CI, 2.76–5.98], adjusted $p < 0.001$) and PFS (HR 3.44 [95% CI, 2.46–4.81], adjusted $p < 0.001$) than those without this DH-TP53 gene expression pattern (Fig. 4). The PFS for DH-TP53-like group was even worse than that described for the DH-TP53 group (HR 1.83 [95% CI, 1.00-3.35], $p = 0.046$; Fig. 4B).

In order to gain more insight into the prognostic value of the TP53 score, we carried out a survival analysis for the most frequent cytogenetic abnormalities, 1q gain, t(11;14), t(4;14) and del(17p), stratifying samples according to whether they belonged to DH-TP53-like group or not. We observed that survival for any of the cytogenetic abnormalities was significantly shortened in the DH-TP53-like group ($p < 0.05$) (Fig. 5).

We also investigated the impact of the DH-TP53-like group on the risk stratification according to International Staging System (ISS). The DH-TP53-like group combined with ISS III had a median PFS and
OS of 11 and 17 months, respectively, whereas for the rest of patients with ISS III median PFS and OS were of 28 and 59 months, respectively ($p < 0.001$). Likewise, median PFS and OS of patients with ISS I/II were reduced from 47 and 95 months to 19 and 50 months, respectively, ($p < 0.001$) when the patients belonged to DH-TP53-like group (Fig. 6).

We performed a multivariable Cox model including the DH-TP53-like group defined by our score, the age at diagnosis and the well-established high-risk prognostic factors in MM, ISS, high-risk cytogenetic abnormalities and DH-TP53 group. The DH-TP53-like group was selected as an independent factor for PFS with the highest HR (HR 3.84 [95% CI 2.51–5.88]; $p < 0.001$) along with DH-TP53 group, age, ISS stage III and 1q gain. The negative impact of DH-TP53-like group was also maintained in the Cox model for OS (HR 3.32 [95% CI, 2.31–4.77]; $p < 0.001$) (Fig. 7).

**Validation of the DH-TP53 score**

Finally, we externally validated the DH-TP53 score in two previously published series: GSE4581 (n = 414) and GSE136400 (n = 436). Both series included microarray gene expression data from NDMM patients. Using these microarray data, we identified 68 and 63 out of the 78 genes of the DH-TP53 score, respectively, which were then used to calculate the score. The survival analysis of these two series clearly showed two curves whose separation widened as the cut-off value decreased. Thus, patients with a higher score, between 5–25% of the validation cohort, in both datasets showed a particularly adverse prognosis compared with the other patients ($p < 0.001$; Additional file 3: Figure S1).

**Discussion**

TP53 abnormalities, although uncommon at the time of diagnosis, remain one of the most important prognostic factors in MM patients, specially when del(17p) and TP53 mutation are present together. p53 might be inactivated by other mechanisms, as has been described in other lymphoid malignancies [18]. In order to ascertain this possibility, we searched for the presence of the transcriptional signature associated with DH-TP53 in NDMM patients who did not present these DNA alterations. Expression signatures of TP53 status have been defined in solid tumors [19, 20]. In MM, previous studies have identified differentially expressed genes related to TP53 expression [21] and a p53 target gene signature associated with TP53 gene aberrations [7]. Recently, the impact of the biallelic inactivation of TP53 on gene expression has been analyzed [8]. The novelty of our study is to demonstrate that there are MM patients with very unfavorable prognosis, which have a transcriptional signature like that of patients with DH-TP53, but without having these TP53 abnormalities. Strikingly, this DH-TP53-like group showed even shorter PFS than DH-TP53 patients considered as ultra-high-risk patients [6].

It should be noted that 60% of patients belonging to DH-TP53-like group were classified into ISS stage III, compared to approximately 30% of DH-TP53 and “other patients” groups. This reflects the high tumor mass and renal function impairment observed in DH-TP53-like patients and highlights the validity of ISS
in discriminating high-risk patients [22], even after the introduction of novel agents. Nonetheless, in the multivariable Cox model, the DH-TP53-like group maintained its independent negative impact on survival.

Cytogenetic alterations do not seem to be the cause of the poor outcomes associated with DH-TP53-like group, as the distribution of International Myeloma Working Group (IMWG)-defined high-risk cytogenetic abnormalities [23] was similar to that found in the “other patients” group. In fact, the adverse prognosis of the patients included in the DH-TP53-like group was not properly captured by the revised-ISS (R-ISS) [24], since up to 67% of DH-TP53-like patients were not classified as high-risk patients. On the other hand, it is noteworthy that patients with 1q gain were over-represented in DH-TP53-like group. In fact, 1q gain was identified as an independent prognostic factor in the multivariable analysis, as has recently been reported in the analysis baseline cohort of the CoMMpass study [25].

More importantly, the combination of DH-TP53-like group and ISS stage significantly improved prediction of outcome in MM. The median OS dropped from 59 months for patients with ISS III to 17 months for patients with ISS III that belonged to DH-TP53 like group.

Despite del(17p) is one of the most consistent high-risk cytogenetic abnormalities included in the main risk stratification models, its negative impact is not observed in some MM patients. In this context, different approaches, such as higher cut-off value for del(17p) [26] and biallelic inactivation of the TP53 gene [6], have been published in an attempt to distinguish those patients with del(17p) who have extremely poor outcome. One of the contributions of this work in this regard is that among the patients with del(17p) it is possible to identify a subgroup without TP53 mutations that have a prognosis as poor as those patients with TP53 biallelic inactivation. Furthermore, our DH-TP53 score refined the prognostic value not only of other cytogenetic abnormalities associated with poor outcome, such as 1q gain and t(4;14), but also of t(11;14), which has been usually linked to favorable outcomes in MM. Thus, patients with 1q gain, t(4;14) or t(11;14) who simultaneously belonged to DH-TP53-like group had significantly shorter PFS and OS.

An interesting finding emerged when the frequency of the most common point mutations in MM was assessed according to the presence of DH-TP53 signature. A significantly greater proportion of MAX gene mutations was observed in DH-TP53-like patients. Loss of function of MAX in MM patients has been associated with the proliferative subtype [25]. The enrichment of MAX mutations in DH-TP53-like patients, who experience a particular poor outcome, deserves to be investigated extensively.

Conclusions

In summary, the DH-TP53 and DH-TP53-like groups share the same transcriptional signature, although the biallelic inactivation of TP53 is only present in the former group. There are at least two possible explanations for this finding. One is that the activity of p53 is attenuated by mechanisms other than DNA alterations, like overexpression of negative regulators; the other explanation is that the combination of other genetic alterations leads to the deregulation of transcriptional pathways that can be superimposed on those deregulated by the biallelic inactivation of TP53 [27, 28]. Hence, the DH-TP53 score described in
this study could be a useful tool for identifying MM patients with p53 dysfunction, bearing in mind that a portion of these patients are not evidenced through FISH and DNA sequencing analysis.
