Abstract

Green synthesis has gained extensive attention in material science because of its sustainability and eco-friendliness in producing a wide range of nanomaterials. This study demonstrated the photocatalytic and antimicrobial abilities of green synthesized silver-embedded zinc oxide nanocomposites (Ag@ZnO NCs). Zinc oxide with a unique mesoporous ellipsoidal morphology in size range of 0.59 ± 0.11 × 0.33 ± 0.09 µm (length × width) was synthesized using the aqueous extract of goji berry (ZnO-GB) by calcination in the air. Powder X-ray diffraction (XRD) revealed the formation of a hexagonal phase of wurtzite (WZ) structure. The average crystallite size of ZnO-GB was 23.74 ± 4.9 nm as calculated using Debye–Scherrer’s equation. It also possesses higher thermal stability with the surface area, pore-volume, and pore size of 11.77 m²/g, 0.027 cm³/g, and 9.52 nm, respectively. Furthermore, different mesoporous Ag@ZnO NCs embedded with face-centered cubic (fcc) silver nanoparticles (Ag NPs) in the range of 90–160 nm were synthesized by GB extract as a reducing and capping agent on the surface of ZnO-GB after calcination. The immobilization of Ag NPs was confirmed by XRD, X-ray photoelectron spectroscopy (XPS), field-emission scanning electron microscopy (FE-SEM), FE-transmission electron microscopy (FE-TEM), and energy-dispersive X-ray spectroscopy (EDS). It was found that Ag₀.₂@ZnO NC (0.2 wt% of Ag) showed excellent photocatalytic degradation of both methylene blue (MB) (cationic) and congo red (CR) (anionic) dyes under simulated solar irradiation. The photocatalytic degradation of 99.3 ± 0.35% MB and 98.5 ± 1.3% CR occurred in 90 and 55 min, respectively, at room temperature by Ag₀.₂@ZnO NC. Besides, these NCs also showed broad-spectrum antibacterial activity against both Gram-positive and Gram-negative bacteria. The mechanistic concept of generating reactive oxygen species (ROS) by electron and hole charge (e⁻/h⁺) carriers seems to be responsible for the photocatalytic degradation of commercial dyes and antibacterial activities by Ag@ZnO NCs. Thus, these as-prepared green Ag@ZnO NCs are promising candidates as photocatalysts for industrial/wastewater treatment as well as in antimicrobial therapeutics.

Introduction

Advanced oxidation processes (AOPs) are widely used technology to remove any organic recalcitrant contaminants/pollutants in wastewater. Generally, AOPs such as Fenton-like processes, ozonation, sonolysis, and photocatalysis are used for the remediation treatments in the aqueous medium. These AOPs utilize strong oxidants such as hydroxyl and superoxide anion radicals for the remediation of pollutants and antimicrobial activity. However, the drawbacks of AOPs are mainly because of their expensive energy sources such as ultraviolet (UV) light or reagents such as ozone and hydrogen peroxide. Thus, the use of solar irradiation as a natural energy source in photocatalysis can reduce the cost of remediation. Photocatalysis is a cost-effective, eco-friendly, and sustainable catalytic process involving light energy as a renewable energy source to activate photocatalysts such as metal or semiconductor nanoparticles to degrade various environmental hazardous pollutants. It is a surface phenomenon that happens mainly on the catalyst’s surface. The photocatalytic efficiency of any nanomaterials is based on their interactions with light, the generation of electron–hole (e⁻/h⁺) pairs, and efficient charge separation.
In the recent past, researchers have used several photocatalysts to degrade several hazardous industrial dyes and pollutants. The dyes are classified into cationic and anionic dyes that can be dissociated into positively and negatively charged ions, respectively, in an aqueous solution. The cationic dyes such as methylene blue (MB), rhodamine B (Rhb), crystal violet (CV), rhodamine 6G (Rh6G), and malachite green (MG), and anionic dyes such as methyl orange (MO), acid orange 7 (AO7), phenol red (PR), eosin Y (EY), congo red (CR), and rose Bengal (RB) are widely used in textile industries and discharged as industrial effluents. Other organic pollutants include glyphosate, carbofuran, picloram, fluometuron, aniline, methamidophos, trichlorfon, turbophos, trichlopyr, erioglaucine, tebuthiuron, and propham. Using photocatalysis, both dyes and other organic pollutants can be mineralized to carbon dioxide and water without any secondary hazardous products.

Metal and semiconductor nanoparticles exhibit unique optoelectronic properties depending on their size and shape for the photoinduced catalytic reactions. Semiconductors such as zinc oxide (ZnO) and titania (TiO$_2$) can act as photocatalysts. Among different semiconductors, ZnO is one of the most common biocompatible transition metal oxide semiconductors of the II-VI semiconductor group used. The low photocatalytic activity of bulk ZnO is due to its quick recombination of charge carriers and comparatively low charge separation. However, ZnO nanoparticles (NPs) with hexagonal wurtzite crystal structure exhibit good photoexcitation stability and high electron mobility. Besides, the nanostructured ZnO with a wide bandgap of 3.37 eV cannot show any absorption upon visible light irradiation. Therefore, the doping of noble metals, metal oxides, metal sulfides, or polymers in the preparation of semiconductor nanocomposites can enhance the absorption in the visible range. In addition, the synthesis of nanomaterials with metal nanoparticles of silver, gold, iron, copper, ruthenium, and palladium on the surfaces of metallic oxides has significant applications in the diverse fields of biosensing, photovoltaics, energy storage, and optics along with catalysis. For instance, semiconductor metal oxide nanoparticles of ZnO NPs exhibit promising applications in photocatalysis, heterogeneous catalysis, and antimicrobial therapy. The UV light-driven photocatalytic activity of ZnO NPs is due to their wide bandgap and high exciton binding energy (60 meV). It is also known to generate reactive oxygen species (ROS), which enhances photocatalytic activity and biomedical applications for antibacterial and photodynamic therapy. The extent of ROS production and the cytotoxicity of ZnO NPs are enhanced by the interaction with cellular components and the release of Zinc cations. Similarly, metal nanoparticles such as silver nanoparticles (Ag NPs) can induce oxidative stress and cellular toxicity by producing ROS species. The surface plasmon resonance (SPR) of Ag NPs can give visible light photocatalysis to Ag/ZnO nanocomposites. The combination of ZnO and Ag together can generate more ROS and provide a cumulative effect on photocatalysis, antibacterial and anticancer activities.

Green synthesis of nanocomposites is emerging as an eco-friendly sustainable methodology for the low-cost synthesis of various metal and semiconductor nanocomposites. Demissie, et al. synthesized ZnO NPs using Lippia adoensis “Koseret” leaf extract and evaluated their antibacterial activity against both Gram-positive (Staphylococcus aureus and Enterococcus faecalis) and Gram-negative (Escherichia
coli and Klebsiella pneumonia) bacteria. Similarly, using the aqueous extract of wolfberry fruit extract, Dong and colleagues green synthesized highly crystalline spherical Ag NPs in the range between 3 and 15 nm. Recently, Chauhan, et al. employed a facile green route to synthesize both ZnO and Ag-doped ZnO using the leaf extract of Cannabis sativa as a reducing and stabilizing agent. These nanoparticles were demonstrated for the photocatalytic degradation of industrial dyes (congo red and methyl orange) and antimicrobial activity. Different morphologies of nanomaterials can be synthesized in a greener route by controlling the synthesis parameters. Herein, we have developed a green methodology to synthesize unique mesoporous ellipsoidal semiconductor particles of zinc oxide (ZnO-GB) and metal/semiconductor nanocomposites of silver@zinc oxide nanocomposites (Ag@ZnO NCs) using the aqueous fruit extract of goji berries (GB) as a reducing and stabilizing agent. ZnO-GB and Ag@ZnO NCs with different silver concentrations have been evaluated for their photocatalytic activity against both anionic and cationic dyes and antibacterial activity against Gram-positive (S. aureus) and -negative (E. coli) bacteria.

**Experimental**

**Materials**

Silver nitrate (AgNO\(_3\), 99%) was purchased from Sigma-Aldrich (USA). Zinc nitrate hexahydrate (extra pure grade), ammonia water, methylene blue (MB), and congo red (CR) were purchased from Duksan Pure Chemicals Co., Ltd. (South Korea). Ampicillin sodium salt was bought from Daejung Chemicals & Metals Co., Ltd. (Siheung, South Korea). Dried goji berries (Lycium barbarum L.) were purchased from Yeongcheon medicinal herb market (Yeongcheon, South Korea). Microorganisms Escherichia coli (KCTC 2571) and Staphylococcus aureus (KCTC 3881) were obtained from the Korean Collection for Type Cultures (Jeongeup, South Korea). Muller–Hinton (MH) broth medium and agar were purchased from Becton, Dickinson, and Company (Sparks, MD, USA). Deionized water was collected using a Milli-Q direct water purification system (Merck Millipore) and used to prepare all solutions.

**Preparation of goji berry (GB) extract**

The aqueous extract of goji berry (GB) (Lycium barbarum L.) fruit was done as mentioned earlier. Briefly, the dried GBs were chopped into small pieces and then excellently ground into a coarse powder in a mortar pestle. The aqueous extract was prepared by heating 5.0 g of GB powder in 100 mL of deionized water taken in a 250 mL Erlenmeyer flask and allowed to boil with stirring at 100 °C for 15 min. Later, the solution was cooled to room temperature and centrifuged at 4,000 rpm for 10 min and filtered through Whatman No. 1 filter paper to obtain a clarified solution of GB extract. Finally, the aqueous GB extract was stored in the refrigerator at 4 °C for the preparation of metal nanoparticles and metal/semiconductor nanocomposites.

**Goji berry-mediated synthesis of zinc oxide particles (ZnO-GB)**

Initially, 8.0 g zinc nitrate hexahydrate was dissolved in 100 mL deionized water and stirred at room temperature for 5 min. Then, 30 mL of freshly prepared GB extract solution was dropwise added, and the
pH of the solution was adjusted to 9.0 using aqueous ammonia. The resultant mixture was continuously stirred for 24 h at 80 °C. The obtained yellow precipitate was collected by centrifugation at 4,000 rpm for 15 min and washed twice with deionized water. The as-prepared GB-mediated zinc oxide (ZnO-GB) particles were dried in a vacuum oven at 60 °C overnight, followed by calcination at 200 °C/2 h and 250 °C/3 h in air and stored in an airtight amber vial.

**Preparation of silver@zinc oxide nanocomposites (Ag@ZnO NCs)**

To prepare different Ag@ZnO NCs, 6.0 g ZnO-GB was added with varying quantities of silver (0.2%, 0.4%, and 0.8%) in 100 mL of deionized water taken in an amber bottle. The solution was sonicated for 30 min to homogeneous the solution containing silver nitrate and ZnO-GB. Then 40 mL GB extract was added dropwise with constant stirring at 60 °C for 3 h. The formed precipitate was washed three times with deionized water after centrifuging at 10,000 rpm for 20 min and dried in a hot air oven at 60 °C overnight. These dried nanocomposite powders were calcined in air at 200 °C/2 h and 250 °C/3 h and stored in an amber vial for further experiments. These nanocomposites with different silver concentrations of 0.2, 0.4, and 0.8% (wt/v) were referred to as Ag$_{0.2}$@ZnO, Ag$_{0.4}$@ZnO, and Ag$_{0.8}$@ZnO NCs, respectively. The pictorial representation of the synthesis of these metal/semiconductor nanocomposites is provided as the schematic diagram (Figure 1).

**Characterization of ZnO-GB and Ag@ZnO NCs**

The optoelectronic properties of ZnO-GB and different Ag@ZnO NCs were determined from the ultraviolet-visible (UV-vis) diffuse reflectance spectra (DRS) recorded using a VARIAN Cary 5000 spectrophotometer (Agilent Technologies, USA) equipped with a Praying Mantis diffuse reflectance accessory (DRA). Powder X-ray diffraction (XRD) analysis was performed to determine the crystalline structure of the nanocomposites using a PANalytical X'PertPRO MPD (Netherlands) X-ray diffractometer with Cu K$_\alpha$1 radiation (0.15406 nm) and operating conditions of tube voltage 40 kV, tube current 30 mA, and scanning between 7.0° and 80.0° (2θ) at a rate of 1.2°/min. The diffraction peaks of the crystalline phases were compared with the standard compounds of the JCPDS data. The average crystallite size (D) of the samples was calculated using the Debye–Scherrer's equation: D = Kλ/βcosθ, where K is Debye-Scherrer constant (0.89), λ is the X-ray wavelength (0.15406 nm), β is the full-width at half maximum (FWHM), and θ is the diffraction angle. Fourier-transform infrared (FTIR) spectroscopy was performed using a Perkin-Elmer FTIR (Model: Spectrum 100) spectrometer in transmittance mode with the wavenumber range of 400–4000 cm$^{-1}$. The hydrodynamic size and zeta potential of the samples were analyzed using Zetasizer nanoparticle analyzer (Malvern Instruments Worc, UK, Model: ZS90) at 25 °C.

To analyze the morphology and composition of the nanocomposites, field-emission scanning electron microscopy (FE-SEM) (Hitachi, Japan, Model: S-4200) was performed by mounting the samples on an aluminum stub and sputter-coated with platinum and analyzed with secondary electron (SE) detectors at operating voltages of 10 and 15 kV and the elemental composition was analyzed by SEM-energy dispersive X-ray spectroscopy (SEM-EDX). The shape and size of the nanocomposites were examined...
using an FE-transmission electron microscope (FE-TEM, FEI Tecnai G2 F20, Oregon, USA) at an accelerating voltage of 200 kV. The elemental analysis of the nanocomposites was also analyzed using the high-angle annular dark-field scanning TEM energy-dispersive X-ray spectroscopy (HAADF-STEM-EDS). The oxidation state of each element of the nanocomposite was analyzed using X-ray photoelectron spectroscopy (XPS) via a Thermo Scientific K-Alpha system with an Al Ka X-ray source and the ion source energy was between 100 V and 3.0 keV for the survey. The thermal stability of nanocomposites was analyzed by thermogravimetric analysis (TGA) from room temperature to 800 °C at a heating rate of 20 °C/min in a nitrogen atmosphere. Photoluminescence (PL) spectroscopy was performed using the HORIBA Scientific Raman system and analyzed with LabSpec 6 software. A 325 nm air-cooled He-Cd laser power at 50 mW with Syncerity CCD and detected with 10× objective in the wavelength range of 340–1050 nm. Brunauer–Emmett–Teller (BET) surface area (S\text{BET}), Barrett–Joyner–Halenda (BJH) pore size distribution, and pore-volume of samples were analyzed using a Micromeritics 3Flex adsorption analyzer (Norcross, GA, USA). The photocatalytic degradation of dyes was evaluated using a Shimadzu UV-2600 dual-beam UV-vis spectrophotometer (Kyoto, Japan).

**Applications of ZnO-GB and Ag@ZnO NCs**

**Photocatalytic degradation of dyes**

The photocatalytic degradation of dyes (MB and CR) by ZnO-GB and Ag@ZnO NCs as photocatalysts was assessed by the decolorization of dye solutions with the initial concentrations of 10 mg/L MB or 20 mg/L CR under simulated solar light irradiation (Osram Ultra-Vitalux, 300 W). In the photocatalysis, 0.1% (w/v) of ZnO-GB and various Ag@ZnO NCs were taken as photocatalysts and added to 100 ml of aqueous dye solutions under continuous stirring. Before simulated solar irradiation, the dye solution with photocatalyst was incubated at room temperature in the dark for 30 min to reach adsorption-desorption equilibrium. The distance between the lamp and the dye solution was kept at 10 cm, and the samples were taken periodically and centrifuged at 12,000 rpm for 10 min to remove the nanocomposites from the dye solutions. The maximum absorbance (λ\text{max}) of the supernatant dye solution was analyzed by a dual-beam UV-vis spectrophotometer to quantify the concentrations of MB and CR dyes at 663 and 498 nm, respectively. The rate of degradation of dyes was calculated by the percentage of the concentration of dye that remained after a specific time over the initial dye concentration.

\[
\text{Degradation (\%)} = \left(\frac{C_0 - C_t}{C_0}\right) \times 100
\]

Where \(C_0\) and \(C_t\) are the initial and final concentrations of dyes at a reaction time (t), respectively.

**Antibacterial assay**

The antibacterial activity of ZnO-GB and Ag@ZnO NCs was tested against both Gram-negative (\textit{E. coli}) and -positive (\textit{S. aureus}) bacteria using the agar well diffusion method. The overnight cultures of \textit{E. coli} and \textit{S. aureus} was obtained by inoculating the MH broth with the pure single colonies of bacteria. Later, the MH agar plates were spread-plated with pure bacterial suspensions, and the agar wells were made...
using a sterile cork-borer with a diameter of 8 mm. Different Ag@ZnO NCs and ZnO-GB (2 mg, 40 mg/ml) were loaded into the wells, and the plates were incubated at 37 °C for 16 h. Ampicillin (300 µg for S. aureus, and 500 µg for E. coli) was used as a positive control. The development of the zone of inhibitions (ZOIs) around the ZnO-GB and Ag@ZnO NCs loaded wells was measured and recorded.

**Results And Discussion**

**Green synthesis of ZnO-GB and Ag@ZnO NCs**

Generally, plant extracts have great potential in the synthesis of nanoparticles and nanocomposites. The aqueous extract of goji berries contains several phytochemicals such as phenylpropanoids, coumarins, lignans, and isoflavonoids providing natural reduction, capping, and/or stabilization moieties over the expensive chemicals to form metal nanoparticles and nanocomposites [21]. During the green synthesis of ZnO-GB, the color of the solution changed to light yellowish and precipitated within 30 min at 80 °C, indicating the formation of ZnO-GB. The possible mechanism involved in the formation of ZnO-GB particles could be that the polyphenols in the GB extract could have acted as ligand agents forming complex ligands with zinc ions, and the stabilized ZnO-GB particles were formed through the process of nucleation and condensation. The excess of bioorganic components attached to ZnO-GB from the GB extract could have been decomposed in the calcination process in air releasing ZnO-GB particles [24,25].

Sadiq, et al. [15] demonstrated the green synthesis of ZnO NPs using the leaf extract of *Syzygium cumini* (black plum). Besides secondary metabolites, plant extracts also contain many biomolecules such as proteins, polysaccharides, terpenoids, and alkaloids that could have been involved in the bioreduction and stabilization of various metal/metal oxide nanoparticles and nanocomposites [26]. When different concentrations of silver (0.2–0.8 wt%) were mixed with ZnO-GB and with the addition of GB extract, the solution color changed to light greenish, denoting the formation of Ag NPs on the surface of ZnO-GB as Ag@ZnO NCs at 60 °C within 3 h (Figure 1). The optical properties of the colloidal solution depend on the nanoscale morphology as well as the distance between them [27]. It has been postulated that the keto-enol tautomeric transformation of polyphenolic compounds of plant extract such as flavonoids may release the reactive hydrogen atoms, which drive the reduction of Ag ions and enable the formation of Ag NPs [28-30]. In addition, the internal conversion of ketones to carboxylic acids in flavonoids was also likely to be involved in the reduction process of silver ions to Ag NPs [31].

**Characterization of ZnO-GB and Ag@ZnO NCs**

The optical properties of the ZnO-GB and Ag@ZnO NCs were investigated by the UV-vis diffuse reflectance absorption spectra. Figure 2a shows the absorption edges of ZnO-GB and Ag@ZnO NCs in the UV region with a band edge at ~372 nm. However, Ag@ZnO NCs with Ag NPs showed better absorption in the visible region from 450 to 550 nm, and the intensity of the absorption in the visible region is solely dependent on the absorption of Ag NPs [32]. The broad bands of NCs in the visible region are mainly due to the surface plasmon resonance (SPR) of Ag NPs indicating the polydispersity nature of nanoparticles.
The increase in the plasmon peak intensity is correlated with the increase in the average size of the Ag NPs, and the absorption band for Ag NPs shifted towards a higher wavelength with the increasing Ag content. The bandgap energies \((E_g)\) of all samples were calculated using the following equation: \(ahv = A(hv-E_g)^n\), where \(E_g\) is the direct bandgap energy, \(a\) is the optical absorption coefficient, \(h\nu\) is the photon energy, \(n\) corresponds to the nature of transition, and \(A\) is the constant. The bandgap energies of all samples were calculated from the Tauc's plot, and the bandgap diagram and values are shown in Figure 2b. The optical bandgap energy of ZnO-GB was 3.1 eV, and the bandgap values of Ag@ZnO NCs decreased with increased Ag NPs binding on the surface of ZnO. The bandgap values were 2.99, 2.93, and 2.88 eV for Ag\(_{0.2}\)@ZnO, Ag\(_{0.4}\)@ZnO, and Ag\(_{0.8}\)@ZnO NCs, respectively. The lower bandgap energies of Ag@ZnO NCs were attributed to the introduction of impurity into the ZnO grains that have trapped excited electrons from the conduction band and promoted continuum of energy level and bandgap narrowing\(^{33}\). Besides, the GB extract components modify/stabilize the surface of NPs and NCs and reduce the bandgap values\(^{34}\).

The purity and crystal structure of ZnO-GB and Ag@ZnO NCs, synthesized by the GB extract, were determined through powder XRD spectra, as shown in Figure 2c. Powder XRD spectra revealed the characteristic \(2\theta\) peaks of ZnO-GB at 31.76°, 34.43°, 36.26°, 47.56°, 56.61°, 62.90°, 66.41°, 67.98°, 69.10°, 72.61°, 77.0° corresponding for (100), (002), (101), (102), (110), (103), (200), (112), (201), (004), and (202) planes of the crystal lattices. This agrees with the polycrystalline diffraction patterns of the hexagonal phase of wurtzite ZnO (JCPDS card No. 89-0510), and no impurity peaks were observed\(^{35}\). Qu, et al.\(^{36}\) demonstrated the synthesis of ZnO NPs with hexagonal wurtzite crystal structure from the Sedum alfredii Hance, a Zinc hyperaccumulating plant. In another instance, a bio-based approach was used to synthesize crystalline and polydispersed ZnO NPs (72.5 nm) using Physalis alkekengi L. to remediation of zinc-contaminated soils\(^{37}\). The average crystallite size of ZnO-GB calculated using the Debye–Scherrer's equation was 23.74 ± 4.9 nm. Also, the strong and sharp diffraction peaks confirm the high crystallinity of ZnO-GB, and the degree of crystallinity was calculated through the equation: \([\text{area of crystalline peaks/area of crystalline & amorphous peaks}] \times 100\), showed 100% crystallinity. Zaid, et al.\(^{38}\) reported that calcination at higher temperatures could improve the crystallinity and better particle distribution. In Ag@ZnO NCs, the additional peaks of 38.11°, 44.30°, and 64.45° correspond to (111), (200), and (220) planes of face-centered cubic (fcc) phase of silver (JCPDS card No. 2-109)\(^{39}\). The ionic radius of silver ion \((\text{Ag}^{+})\) (0.122 nm) was larger than that of zinc divalent \((\text{Zn}^{2+})\) ions, thus silver ions cannot be substituted into the crystal lattice of the ZnO matrix, therefore, the metallic silver peaks due to the Ag NPs are formed over the ZnO surface\(^{33}\). The FWHM and crystallite size are inversely proportional, therefore, the increase in the size of Ag NPs results in the formation of larger NCs. These Ag NPs formed on the surface of ZnO-GB were in the size of 25.65 ± 5.0, 32.91 ± 3.3, and 33.32 ± 4.21 nm diameter for Ag\(_{0.2}\)@ZnO, Ag\(_{0.4}\)@ZnO, and Ag\(_{0.8}\)@ZnO NCs, respectively. The intensity of Ag NPs peaks increases with the increase in the silver content of NCs, which is due to the increase in the number of Ag NPs on the surface of ZnO.
The functional groups involved in the formation of ZnO-GB and Ag@ZnO NCs were investigated by the Fourier-transform infrared (FTIR) spectroscopy in the range of 400–4000 cm\(^{-1}\) (Figure 2d). FTIR spectra of all samples and GB extract exhibited various absorption bands. In GB extract spectrum, the broad band centered at 3290 cm\(^{-1}\) was assigned to hydrogen-bonded O–H stretching vibrations, and the weak signal at 2936 cm\(^{-1}\) was due to C–H stretching vibrations. The band at 1595 cm\(^{-1}\) was attributed to the C–OH deformation vibration, and the band at 1417 cm\(^{-1}\) was due to the O–C–O symmetric and asymmetric stretching vibrations of the carboxylate group. Moreover, the band at 1025 cm\(^{-1}\) was assigned to C–O stretching vibrations of the pyranose ring. The FTIR spectra of GB extract synthesized ZnO-GB and Ag@ZnO NCs exhibited a difference from the GB extract spectrum. The intensity of broad band around wavenumber 3396 cm\(^{-1}\), the characteristic of OH stretching vibration, decreased in all samples after calcination. Meanwhile, the broad absorption bands around 400-600 cm\(^{-1}\) were attributed to the stretching modes of metal-oxygen bonds, thus confirming the formation of Zn–O bonds.

Dynamic light scattering (DLS) is a relatively robust and economical technique to measure the average size and size distribution of green synthesized nanoparticles and nanocomposites. Mainly, DLS provides larger values because of the hydrodynamic shell, which is dependent on the structure, shape, and roughness of the particles. According to Stokes-Einstein (SE) equation, the measured diffusion coefficients are related to the hydrodynamic radius as: 
\[ D = \frac{k_B T}{6\pi\eta R_h} \]

where \( k_B \) is Boltzmann’s constant (1.38 \times 10^{-23} J/K), \( T \) is the temperature, \( \eta \) is the viscosity of the suspension medium, and \( R_h \) is the hydrodynamic radius. There was an increase in the size of nanocomposites with the addition of silver to ZnO-GB (Figure 3a-d). The increase in the size can be caused by the formation of Ag NPs on the surface of ZnO particles and the aggregation of NCs. The zeta (\( \zeta \)) potential is used to study the surface charges and stability of nano- or submicronic particles. The biomolecules from the GB extract were involved in reducing and stabilizing nanoparticles and nanocomposites. The zeta potential was calculated by dispersing the particles in water as the dispersion medium. The values of zeta potential were correlated with their stabilities: 0 to ± 5 (rapid coagulation), ± 10 to ± 30 (incipient stability), ± 30 to ± 40 (moderate stability), ± 40 to ± 60 (good stability), and > ± 61 (excellent stability). The average zeta potential of green synthesized ZnO-GB after calcination was +2.72 mV indicating positively charged groups in the stabilization. However, the zeta potentials of Ag\(_{0.2}\)@ZnO, Ag\(_{0.4}\)@ZnO, and Ag\(_{0.8}\)@ZnO NCs were −16.4, −28.1, and −0.46 mV, respectively (Figure 3e-h). This shows that with the increase in the formation of Ag NPs on the surface of ZnO-GB, the stability of Ag\(_{0.2}\)@ZnO and Ag\(_{0.4}\)@ZnO NCs increases, whereas the stability decreases with Ag\(_{0.8}\)@ZnO NC.

The surface morphology of ZnO-GB and various Ag@ZnO NCs, green synthesized by GB extract, were identified using FE-SEM. It can be noticed that most of the ZnO-GB showed clusters of ellipsoidal-like morphology on a submicronic scale. The ellipsoidal-like particles were in the size of 0.7 ± 0.13 and 0.38 ± 0.075 µm (length \( \times \) width) (Figs. 4a and b). Remarkably, all ZnO-GB were almost identical in dimension, and the surface looks puffy with an irregular pattern of pillar ridges. There was a slight agglomeration of particles due to the slightly higher surface area and durable affinity among ZnO-GB particles.
morphologies of ZnO NPs, for example, nanospheres, nanoflower, nanoflakes, nanobelt, nanorods, nanowires, nanoneedles, nanotubes, and nanorings, can be synthesized by controlling the synthesis parameters \(20,48,49\). The addition of silver with GB extract formed spherical Ag NPs i.e., 0.06 ± 0.011, 0.09 ± 0.04, 0.14 ± 0.045 µm for \(\text{Ag}_{0.2}@\text{ZnO}\), \(\text{Ag}_{0.4}@\text{ZnO}\), and \(\text{Ag}_{0.8}@\text{ZnO}\) NCs, respectively, on the surface of ZnO particles. There was no significant change in the morphology of Ag@ZnO NCs except with the size of embedded Ag NPs on the surface of ZnO, which increased with the increase in the silver content added to the NCs (Figure 4c-h).

The elemental composition of ZnO-GB and Ag@ZnO NCs were analyzed using the FE-SEM-EDX spectra, as shown in Figure 5. The spectrum of ZnO-GB particles showed a low energy peak at approximately 0.533 keV (O-K\(\alpha\)) due to the presence of oxygen atom, and other peaks for zinc and carbon atoms appearing at about 1.02 keV (Zn-L\(\alpha\)), 8.6 keV (Zn-K\(\alpha\)), 9.5 keV (Zn-K\(\beta\)), and 0.285 keV (C-K\(\alpha\)). In contrast, Ag@ZnO NCs spectra contain intense low energy silver peaks at approximately 2.61 keV (Ag-K\(\alpha\)), 3.0 keV (Ag-L\(\alpha\)), 3.2 keV (Ag-L\(\beta\)), and 3.4 keV (Ag-L\(\beta^2\)) along with Zn, O, and C peaks \(50\). The EDX quantified silver, and other elements content in various Ag@ZnO NCs is shown in Figure 5 (inset). The weight percent of silver increases from \(\text{Ag}_{0.2}@\text{ZnO}\) to \(\text{Ag}_{0.8}@\text{ZnO}\), which infers the successful incorporation of silver as Ag NPs on ZnO-GB \(51\). Hence, the weight percentage of silver embedded on ZnO is proportional to the Ag concentration added to ZnO-GB in the preparation of different Ag@ZnO NCs.

FE-TEM analysis of ZnO-GB and different Ag@ZnO NCs are shown in Figure 6. Agglomeration of ellipsoidal-like ZnO-GB submicronic particles and the formation of spherical Ag NPs on the ZnO-GB surface was further verified by the FE-TEM results. It was found that ZnO-GB was about 0.6 ± 0.11 and 0.33 ± 0.087 µm (length × width), whereas \(\text{Ag}_{0.2}@\text{ZnO}\), \(\text{Ag}_{0.4}@\text{ZnO}\), and \(\text{Ag}_{0.8}@\text{ZnO}\) NCs have Ag NPs in the size of 87 ± 55, 130 ± 43 and 160 ± 55nm, respectively. Furthermore, these results corresponded to the poor correlation between the FE-TEM sizes and particle size distribution analysis. With the increase in the silver content in the NCs, there was an occurrence of large particles due to the aggregation of small or primary particles. The ‘\(d\)’ spacing of ~0.281 nm between the adjacent lattice planes could be attributed to the (002) plane of ZnO-GB (Figure 6-d3). Similarly, the lattice fringes with \(d = \sim 0.24\) nm could be attributed to the (111) planes of Ag NPs (Figs. 6-b3 and c3). All these results confirmed the successful formation of Ag NPs on the surface of ZnO-GB. The \(d\)-spacing of (002) plane of ZnO-GB in Ag@ZnO NC is like that of undoped ZnO, suggesting that Ag\(^+\) ions are not incorporated into the ZnO lattice. SAED pattern of ZnO-GB clearly showed well-resolved diffraction rings indicating the polycrystallinity, and Ag NPs on ZnO-GB (Ag@ZnO NCs) showed bright spots indicating the monocrystalline nature.

Figure 7 shows the HAADF-STEM image of the \(\text{Ag}_{0.2}@\text{ZnO}\) NC and its corresponding elemental composition (Zn-K, Zn-L, O-K, Ag-K, and Ag-L) by STEM-EDX mapping. These images confirm the successful embedment of Ag NPs on the surface of ZnO-GB.

XPS analysis was performed to clarify the chemical states of elements in Ag@ZnO NCs. The full scan survey of \(\text{Ag}_{0.2}@\text{ZnO}\) NC shows the signals from Zn, O, and Ag elements with their corresponding atomic
percent of 38.88, 37.34, and 1.63% in the range 0–1350 eV (Figure 8a). Figure 8b shows the high-resolution spectra of Zn 2p. The peaks of Ag$_{0.2}$@ZnO NC were located at 1021.28 eV and 1044.38 eV, which were ascribed to Zn 2p$_{3/2}$ and Zn 2p$_{1/2}$, respectively. These peaks confirm that the Zn element exists in a divalent cation (Zn$^{2+}$) state in the NC. Figure 8c shows the high-resolution O 1s peak of Ag$_{0.2}$@ZnO NC. The deconvoluted O 1s peak shows two subpeaks at binding energies of 529.8 and 531.2 eV attributing to the lattice oxygen of ZnO-GB and dissociated oxygen or hydroxyl-like group on the surface of ZnO-GB, respectively 52,53. The presence of surface hydroxyl groups acts as adsorption sites of dyes and reacts with photogenerated holes forming hydroxyl radicals by oxidation, which decomposes dyes during photodegradation 54. Therefore, the presence of a surface hydroxyl group with 28.9% was one of the critical factors in the photodegradation process. Figure 8d shows the high-resolution spectrum of Ag 3d photoelectron peaks of Ag$_{0.2}$@ZnO NC. The Ag 3d spectrum shows two peaks centered at 367.38 and 373.48 eV ascribed to Ag 3d$_{5/2}$ and Ag 3d$_{3/2}$ transitions, respectively. The difference in the binding energy of ~6.0 eV between Ag 3d$_{5/2}$ and Ag 3d$_{3/2}$ peaks was the characteristic of metallic silver and consistent with the results of XRD analysis 21,55.

Figure 9a shows the thermogravimetric (TG) analysis of ZnO-GB, Ag$_{0.2}$@ZnO, Ag$_{0.4}$@ZnO, and Ag$_{0.8}$@ZnO NCs. TG analysis was performed from room temperature to 800 °C at a rate of 20 °C/min in a nitrogen atmosphere to demonstrate the thermal stabilities of ZnO-GB and Ag@ZnO NCs. The overall weight loss for all samples was very minimal. A total weight loss of 3.0, 1.6, 0.3, and 0.7% occurred for ZnO-GB, Ag$_{0.2}$@ZnO, Ag$_{0.4}$@ZnO, and Ag$_{0.8}$@ZnO NCs, respectively, and all NCs are highly thermally stable. In ZnO-GB, at the low-temperature range (up to 90 °C), the weight seems to have increased due to the OH bonding with the reaction with moisture. Further, the weight loss up to 350 °C, accounting for ~0.83% was attributed to the loss of H$_2$O molecules and evaporation of gases that were physically and chemically adsorbed on the surface of ZnO-GB particles 56. This explains that ZnO-GB absorbs nitrogen and slowly releases them over a period, which indicates that ZnO-GB was pure and very porous in nature 57. The weight loss accounting ~2.1% from 350 to 700 °C was higher with ZnO-GB, this could be due to the thermal decomposition of biomolecules of GB extracts, such as phenolic compounds and other metabolites. Above 700 °C, there was no significant weight loss in ZnO-GB. A similar decomposition pattern was observed with Ag$_{0.2}$@ZnO NC, however, the embedment of silver slightly improved the thermal stability and decomposition of Ag$_{0.2}$@ZnO NC compared to that of ZnO-GB. In Ag$_{0.4}$@ZnO, and Ag$_{0.8}$@ZnO NCs, the continuous decrease in weight in the nitrogen environment was attributed probably to the oxygen out-diffusion from the ZnO matrix resulting in the formation of oxygen-deficient ZnO compound (ZnO$_{1-\delta}$).

PL spectrum is a valuable tool to investigate the state of photogenerated e$^-$/h$^+$ pairs and the defects of metal/semiconductor nanocomposites 58. Figure 9b shows the PL spectra of ZnO-GB and Ag@ZnO NCs at room temperature. There are two distinct emission peaks at the UV region (~380 nm) and visible region (~400–750 nm). These emission peaks provide information about the recombination between charge carriers and defect levels 17. The emission peak at ~380 nm in ZnO-GB corresponds to near band edge
emission (NBE), attributed to bandgap excitation \(^{59}\). The broad band emission extending from \(-400\) nm to \(-750\) nm in the whole visible spectrum can be from deep-level emission (DLE), i.e., because of crystal defects like Zn-interstitials and oxygen vacancies \(^{43,60}\). All Ag@ZnO NCs showed decreased PL intensity than ZnO-GB, which suggests that the decrease in the recombination rate of photoinduced electrons and holes with the embedment of Ag NPs favoring the photocatalytic activity than ZnO-GB \(^{61}\). The PL intensity of Ag\(_{0.2}\)@ZnO NCs decreased drastically with the increase in the silver content in the NCs providing the separation of photoinduced \(e^-/h^+\) pairs and inhibiting the recombination of photoinduced pairs \(^{62,63}\). However, at Ag\(_{0.8}\)@ZnO NC, with the increase in the Ag concentration, there was no increase in the PL intensity and overlapped with the peaks of Ag\(_{0.4}\)@ZnO NC, suggesting the formation of new recombination centers, which are unfavorable to the separation of photoinduced pairs \(^{58,64}\). Thus, Ag\(_{0.8}\)@ZnO NCs exhibited the lowest PL intensity as that of Ag\(_{0.4}\)@ZnO NC because excess addition of silver as Ag NPs in Ag\(_{0.8}\)@ZnO NC was unfavorable for charge separation.

To determine the structural and adsorption parameters of ZnO-GB and Ag\(_{0.2}\)@ZnO NC, nitrogen (N\(_2\)) adsorption-desorption isotherms at 77 K were recorded. Figure 10a shows the N\(_2\) adsorption-desorption isotherms of ZnO-GB and Ag\(_{0.2}\)@ZnO NC. According to IUPAC classification, these curves obtained for evaluating surface area were approximately identical to that of Type IV isotherm with H\(_3\) hysteresis loop \(^{65}\). The well-defined inflection around relative pressure (P/P\(_0\)) of 0.5–0.9 indicates the presence of a heterogeneously distributed mesoporous nature of particles \(^{66}\). The BET surface area (\(S_{BET}\)) was determined from isotherms using the BET equation \(^{67}\). The values of \(S_{BET}\) were found to be 11.77 and 7.5 m\(^2\)/g for ZnO-GB and Ag\(_{0.2}\)@ZnO NC, respectively, and the mesoporous material contains narrow pores that hinder the movement of nitrogen and limits the adsorption. The \(S_{BET}\) of Ag\(_{0.2}\)@ZnO NC decreased with the embedment of Ag NPs than ZnO-GB, revealing that the formed Ag NPs could have occupied and blocked the pores of ZnO-GB. Figure 10b shows the pore size distribution curve obtained using the Barrett–Joyner–Halenda (BJH) model. It could be seen that most of the pores were in the size range of 2–40 nm, which provides evidence for the mesoporosity framework of ZnO-GB and Ag\(_{0.2}\)@ZnO NC. The BHJ average pore sizes of ZnO-GB and Ag\(_{0.2}\)@ZnO NC were 9.52 and 11.57 nm, respectively, and the calculated mean pore volumes were 0.027 and 0.023 cm\(^3\)/g. The \(S_{BET}\), BHJ mean pore size, and pore-volume of Ag\(_{0.2}\)@ZnO NC were lower than that of ZnO-GB because of the embedment of Ag NPs on the surface of ZnO-GB.

**Mechanism of photocatalytic activity**

The schematic diagram of the photocatalytic degradation of dyes MB and CR by ZnO-GB and Ag@ZnO NCs is proposed in Figure 10c. The advanced oxidation processes (AOPs) generate ROS of highly reactive species such as superoxide anion radicals (\(\cdot O_2^-\)), and hydroxyl radicals (\(\cdot OH\)) are mainly involved in the degradation and mineralization of dyes into carbon dioxide (CO\(_2\)) and water \(^{68}\).
When ZnO is irradiated by the UV light of the simulated solar lamp, electrons in the valence band (VB) get excited to the conduction band (CB), leaving behind holes in the VB. These photogenerated electrons get transferred to the Ag NPs as the CB energy level of ZnO-GB is higher than the Fermi level (E_F) of metallic Ag, which hinders the recombination and extends the lifetime of photogenerated (e^-/h^+) pairs, whereas Ag NPs in the NCs absorb visible light undergo surface plasmon resonance (SPR), and these excited electrons in the 3d orbit of Ag NPs get easily transferred to CB of ZnO-GB owing to the interface effect of Ag/ZnO heterojunctions, yielding more superoxide anion radicals. The holes formed by the excitation of electrons will generate •OH radicals by oxidation of hydroxyl ions. Thus, the as-formed superoxide anion radicals and hydroxyl radicals are mainly responsible for the effective mineralization of dyes into CO_2 and water. The increase of silver amount on the surface of ZnO-GB decreases the photocatalytic degradation efficiency. The decrease in the photocatalytic degradation by Ag_{0.4}@ZnO and Ag_{0.8}@ZnO NCs could be due to the hindrance in the absorption of light by the excess of Ag NPs, which is in agreement with the PL results.

**Applications of ZnO-GB and Ag@ZnO NCs**

**Photocatalytic degradation of dyes**

Photocatalysis happens on the surface of the photocatalyst, and the photocatalytic performance of ZnO-GB was ameliorated by increasing surface-to-volume ratio and by modifying the band structure by the incorporation of Ag NPs to improve the visible-light absorption properties and thereby efficiently restricting the recombination of photogenerated (e^-/h^+) pairs. The photocatalytic properties of ZnO-GB and Ag@ZnO NCs were evaluated via the degradation of dyes MB (cationic) and CR (anionic) under the simulated solar lamp. Figure 11a shows the UV-vis absorption spectra of the degradation of MB with time in the presence of ZnO-GB and Ag@ZnO NCs. Figure 11c shows the photocatalytic degradation (C_t/C_0) as a function of time, where C_t is the concentration of MB at time “t”, and C_0 is the initial concentration. The experimental solution containing the MB (1.0 mg/100 ml) and photocatalyst (0.1% w/v) was allowed for the adsorption-desorption equilibrium in the dark for 30 min, and the MB dye in the range of 3.0 ± 2.5–12.7± 4.2% was adsorbed on ZnO-GB and Ag@ZnO NCs. The increase of silver content as Ag NPs on ZnO increased the adsorption of MB dye on its surface. Moreover, the strong MB dye adsorption capacities by Ag@NCs in the dark improved their photocatalytic performances in terms of their decolorization and degradation processes. The degradation percentage of MB by ZnO-GB, Ag_{0.2}@ZnO, Ag_{0.4}@ZnO, and Ag_{0.8}@ZnO NCs were 89.4 ± 2.2, 99.2 ± 0.34, 97.6 ± 0.91, and 96.0 ± 0.1.5%, respectively after irradiation for 90 min (Figure 11e). Ag_{0.2}@ZnO as photocatalysts showed higher photocatalytic degradative activity than other NCs and ZnO-GB, and it showed 100% degradation in 90 min. However, other Ag@ZnO NCs and ZnO-GB showed ~100% photocatalytic degradation in 120 min. The higher photocatalytic activity by Ag_{0.2}@ZnO NC suggests that adding silver to ZnO-GB improves the photocatalytic activity significantly.
Similarly, the UV-vis absorption spectra of the degradation of CR dye with time by ZnO-GB and different Ag@ZnO NC were shown in Figure 11b. The $C_t/C_0$ degradation of CR versus time was shown in Figure 11d. After incubation at dark for attaining adsorption-desorption equilibrium, CR dye of 26.0±0.77–74.4±1.3% was adsorbed onto ZnO-GB and Ag@ZnO NCs. ZnO-GB had a strong adsorption ability of CR on its surface, however, with an increase in the silver amount, the adsorption of CR on the surface of NCs decreases. Moreover, the strong adsorption capacities of ZnO-GB and Ag@ZnO NCs in the dark improved their photocatalytic performances in their decolorization and degradation processes. The degradation percentages of CR by ZnO-GB, Ag$_{0.2}$@ZnO, Ag$_{0.4}$@ZnO, and Ag$_{0.8}$@ZnO NCs were 92.9±0.5, 98.4±2.4, 92.5±1.5, and 86.1±1.5%, respectively after irradiation for 55 min (Figure 11f) (Table 1). Analogous to MB degradation, the degradation of CR by Ag$_{0.2}$@ZnO NC was higher than other Ag@ZnO NCs and ZnO-GB. The photolysis of dyes without photocatalyst was also determined. Both dyes are barely degraded without photocatalyst, which indicates that both MB and CR dyes are stable in the aqueous environment under simulated solar irradiation. However, CR appears to be more stable than MB under the experimental conditions. There was photolysis of 26.97% and 4.26% for MB and CR dyes, respectively, after irradiation for 150 and 210 min (Supplementary Figure 1 and 2).

Antibacterial assay

Figure 12 shows the antibacterial activity of ZnO-GB and other Ag@ZnO NCs against Gram-positive (S. aureus) and Gram-negative (E. coli) bacteria. The antibacterial activity was evaluated using the agar well diffusion method, which shows that both E. coli and S. aureus were susceptible to all Ag@ZnO NCs. However, E. coli showed slight resistance towards the antimicrobial activity by ZnO-GB and Ag@ZnO NCs. The zones of inhibitions (ZOIs) for Ag$_{0.2}$@ZnO, Ag$_{0.4}$@ZnO, and Ag$_{0.8}$@ZnO NCs were 11.0 ± 0.4, 11.4 ± 0.5, and 11.3 ± 0.6 mm, respectively, for E. coli, whereas it was 13.8 ± 0.6, 14.4 ± 1.0, and 14.6 ± 0.9 mm for S. aureus. Moreover, ZnO-GB showed a marginal ZOI of 10.2 ± 0.4 mm only in S. aureus. The ZOIs for the positive control (ampicillin) were 12.6 ± 0.5 and 25.6 ± 0.7 mm for E. coli and S. aureus, respectively. Our previous study found that GB extract does not possess antibacterial activity against E. coli and S. aureus$^{21}$. Thus, all Ag@ZnO NCs at a 2 mg (0.05 mL) concentration exhibited broad-spectrum antibacterial activity against both E. coli and S. aureus. The antibacterial activity of the ZnO-GB is most likely due to the release of ROS on the surface of ZnO-GB, which causes the disruption of the bacterial membrane, in particular, the production of hydrogen peroxide (H$_2$O$_2$) penetrates the cell membrane and kills the microorganism$^{75,76}$. Gunalan et al. (2012) demonstrated the antibacterial activity of Aloe leaf extract-mediated synthesis of nano-ZnO against S. aureus, Serratia marcescens, Proteus mirabilis, and Citrobacter freundii$^{77}$. Even Ag NPs in Ag@ZnO NCs can cause membrane permeation and bacterial ROS production for the synergistic antibacterial activity with ZnO-GB particles in the nanocomposite$^{78,79}$. Zare, et al.$^{80}$ evaluated the antibacterial potency of ZnO-Ag NC on bacteria. They proposed that physical interaction with bacterial cells causes disruption of cell membrane and oxidization of cell components for exhibiting broad-spectrum antibacterial activity against multidrug resistant bacteria.
Conclusions

The green synthesis of zinc oxide particles (ZnO-GB) using goji berry extract and subsequent calcination in air produced mesoporous elliptical-like morphology with 0.59 µm (length), and 0.33 µm (width) was found to be of hexagonal wurtzite crystal structure. The formation of silver nanoparticles on the surface of ZnO-GB in the formation of Ag@ZnO nanocomposites using the GB extract provides a green method of synthesizing highly porous metal/semiconductor NCs. The presence of polyphenols in the GB extract acts as both reducing and capping/stabilizing agents in preparing nanoparticles and/or nanocomposites. The as-prepared Ag@ZnO NCs were characterized by several techniques, such as FT-IR, XRD, FE-SEM, TEM, EDS, XPS, and UV-vis spectroscopy. The XRD analysis and SEM-EDX and TEM micrographs confirmed the formation of Ag NPs on the surface of ZnO. The photocatalytic activity of Ag$_{0.2}$@ZnO nanocomposite towards both MB and CR degradation in an aqueous medium was found to be higher than that of ZnO-GB and other Ag@ZnO NCs at room temperature. The presence of Ag on the surface of ZnO promotes the separation of photogenerated charge carriers and enhances photocatalysis. In addition, they also showed good antibacterial activity against *Staphylococcus aureus* and *Escherichia coli*. The photocatalysis and antibacterial activity of Ag$_{0.2}$@ZnO are remarkably improved due to the generation of abundant ROS than that of ZnO-GB and other Ag@ZnO NCs. This simple green synthetic methodology provides unique morphological metal/semiconductor nanocomposites for wastewater treatment by photocatalysis and antimicrobial therapeutics.
