Abstract

Background

The aim of this study was to compare conventional suture with prolonged timing of drainage with quilting suture on the formation of seroma at pectoral area after mastectomy (ME) with sentinel lymph nodes biopsy (SLN) or axillary lymph nodes dissection (ALND) for breast cancer.

Methods

388 consecutive breast cancer patients were retrospectively analyzed and categorized into three groups. Patients in group 1 were with quilting suture, group 2 with conventional suture and 13-15 days drainage *in situ*, and group 3 with conventional suture and 20-22 days drainage. The primary outcome was the incidence of Grade 2 and 3 seroma at anterior pectoral area within one month postoperatively. Cox regression was used for analysis.

Results

The incidence of Grade 2 and 3 seroma was comparable among groups (9.5% vs. 7.9% vs. 5.3%, $p = 0.437$), as well as late Grade 2 and 3 seroma among groups (4.3% vs. 2.9% vs. 1.5%, $p = 0.412$). Old age, high body mass index and hypertension were independently risk factors for Grade 2 and 3 seroma.

Conclusions

Prolonged timing of drainage to 13-15 days in conventional suture was long enough to decrease the incidence of Grade 2 and 3 seroma as lower as that in quilting suture group at pectoral area within one month after mastectomy.

Background

The incidence of breast cancer is increasing year by year in China, and mastectomy with SLN or ALND dissection is the most popular surgical treatment for it [1]. The seroma in axilla and dead space beneath skin flaps after surgery would lead to discomfort, repeat visit to outpatient clinics and surgical site infection [2]. Many clinical studies have tried various methods to lower seroma formation, such as suction drainage, shoulder immobilization, quilting sutures, fibrin sealants and thrombin sealants [3–6].

In our previous retrospective study, we focus on the seroma in the dead space at the pectoral area [7]. We showed that quilting suture applied at medial and inferior border of the dead space at the pectoral area could reduce the incidence of Grade 2 and 3 seroma compared with the conventional suture. Furthermore we found that quilting suture could significantly lower the incidence of late Grade 2 and 3 seroma which occurred after the removal of drainage system, rather than the early Grade 2 and 3 seroma. In order to lower the incidence of late Grade 2 and 3 seroma, we tried to prolong the time of drainage and explore the best time point of drainage removal in this study.

Methods

Patients

We retrospectively analyzed 388 consecutive breast cancer patients who underwent ME plus SLN or ALND between September 2017 and August 2020 in the Breast Surgery Department of Xiangya Hospital, Central South University, Changsha City, R.P. China. Patients treated with bilateral breast mastectomy surgery, breast conserving surgery, breast reconstruction surgery, skin grafting, and patients with scleroderma or systemic lupus erythematosus were excluded. All patients were female and local citizens older than 18 years and were first diagnosed as breast invasive carcinoma or ductal carcinoma *in situ*. Patients were divided into 3 groups. During September 2017 to January 2019, 116 patients in group 1 with quilting suture were included for analysis and these patients were also enrolled in our previous study [7]. The drainage system was removed 5–9 days postoperatively in these patients with quilting technique. During February 2019 and October 2019, 139 patients in group 2 with conventional suture and drainage system removal around 13–15 days postoperatively were included in this study. During November 2019 and August 2020, 133 patients in group 3 with conventional suture and drainage system removal around 20–22 days postoperatively were included in this study. Patients data such as age, BMI, medical history, familial history of cancer, TNM stage, and surgical method *et al.* were collected from electronic medical record. This study was reviewed by Institutional Ethical Review Board of Xiangya Hospital.

Surgical Technique

The procedure of surgical technique was described in our previous study [7]. All the patients had a closed suction drain in axillary area. Patients with quilting suture were in group 1, and the skin flaps were sutured to the underlying pectoralis major without a drainage for this area. The drainage in axilla was removed around 5–9 days postoperatively. For conventional wound suture in group 2 and 3, the skin flaps were not fixed subcutaneously. There were two drainages, one for axilla and one for the dead space at the pectoral area. The two drainages were removed 13–15 days in group 2 or 20–22 days in group 3 postoperatively.

All patients were discharged 5–9 days postoperatively after they had received the first cycle of chemotherapy if needed. The follow-up visit was recommended at least twice within 1 month after operation or one week after removal of drainage, and physical and/or ultrasound examination were recommended during the visit.

Outcomes

The primary outcome in this study was the incidence of Grade 2 and Grade 3 seroma in the pectoral area within 1 month postoperatively. We applied the criteria for adverse events classification (CTCAE) 4.0 to categorize the seroma into Grade 1, Grade 2 and Grade 3 which were described as that in our previous study. The secondary outcomes were the overall (Grade 1, 2 or 3) seroma rate in the pectoral area, rate of

wound hematoma indicated with intervention of puncture or surgery, surgical site infection, inadequate wound healing, hospital stay after surgery (days), and drainage volume (milliliters). We categorized seroma into early or late seroma according to the drainage removal time. Early seroma was defined as seroma formed before removal of drainage, and late seroma was defined as seroma formed after removal of drainage at any time but within 1 month postoperatively. Only the seroma at the pectoral area was recorded in this study.

Influence-on-life Assessment

A total of 18 patients in group 2 and 3 with Grade 2 and 3 seroma were assessed. 3(16.7%) patients had the feeling that drainage *in situ* had a great impact on their life. 1(5.6%) patient would like to choose aspiration other than prolong the time of drainage *in situ*. Most patients had acceptable discomfort (83.7%) and would like to prolong the time of drainage *in situ* to avoid or decrease the incidence of Grade 2 and 3 seroma (94.4%) as shown in Table 5.

Results

Patient characteristics

The study enrolled 116 patients in group 1 with quilting suture but without drainage of pectoral area and 139 patients in group 2 with drainage of pectoral area which was removed 13–15 days postoperatively and 133 patients in group 3 with drainage removal 20–22 days postoperatively. The patient characteristics were similar among these three groups (Table 1).

Outcome Comparisons

Outcome comparisons

The incidence of Grade 2 and 3 seroma within 1 month after operation was similar in group 1, group 2 and group 3 (9.5% vs. 7.9% vs. 5.3%, $p = 0.437$). The rates of early or late seroma in Grade 2 and 3 were not significantly different among the three groups ($p = 0.837$ or 0.412 , respectively) as shown in the Table 2. The incidence of Grade 1 seroma was comparable among the three groups ($p = 0.780$).

Table 2
Binary-outcome comparisons

		Quilting Suture (group 2) n = 116	Conventional Suture (group 2) n = 139	Conventional Suture (group 3) n = 133	<i>P</i> value
Seroma (Grade 1, early)	n(%)	14(12.1)	12(8.6)	12(9.0)	0.612
Seroma (Grade 2–3, early)	n(%)	6(5.2)	7(5.0)	5(3.8)	0.837
Seroma (Grade 1, late)	n(%)	7(6.0)	9(6.5)	6(4.5)	0.767
Seroma (Grade 2–3, late)	n(%)	5(4.3)	4(2.9)	2(1.5)	0.412
Seroma (Grade 1)	n(%)	21(18.1)	21(15.1)	18(13.5)	0.780
Seroma (Grade 2–3)	n(%)	11(9.5)	11(7.9)	7(5.3)	0.437
Seroma	n(%)	32(27.6)	32(23.0)	25(18.8)	0.258
Hematoma	n(%)	5(4.3)	5(3.6)	3(2.3)	0.654
Surgical site infection	n(%)	4(3.4)	2(1.4)	2(1.5)	0.251
Inadequate wound healing	n(%)	2(1.7)	2(1.4)	3(2.3)	0.580
Discrete variables used χ^2 test or Fisher exact test.					

There were no significant differences among the three groups regarding hematoma, surgical site infection, inadequate wound healing and length of hospital stay after operation (Tables 2 and 3). Patients treated with quilting suture were more likely to experience less volume of drainage than those in group 2 and group 3 with conventional suture (374.9 vs. 439.1 vs. 461.4 ml, $p < 0.001$) as shown in the Table 3.

Table 3
Continuous outcome comparisons

		Quilting Suture (group 2) n = 116	Conventional Suture (group 2) n = 139	Conventional Suture (group 3) n = 133	P value
Hospital stay after surgery (days)	Mean(SD)	7.8(1.0)	7.9(1.0)	7.7(1.1)	0.609
Drain volume (ml)	Mean(SD)	374.9(57.1)	439.1(66.9)	461.4(82.3)	< 0.001

SD: standard deviation; Continuous variables used *one-way anova* test.

Risk Factors

A multivariate logistic regression was used to evaluate the risk factors of Grade 2 and 3 seroma formation as shown in Table 4. Old age, high BMI and hypertension were found to be risk factors for Grade 2 and 3 seroma. Patients younger than 60-year-old or with BMI less than 25 or without hypertension experienced much less Grade 2 and 3 seroma within 1 month postoperatively when compared to patients older than 60 or with BMI higher than 25 or with hypertension ($p < 0.05$). Diabetes, neoadjuvant chemotherapy and type of suture had no influence on developing a Grade 2 and 3 seroma in the pectoral area.

Table 4
Risk factors for seroma (Grade 2–3)

Parameter	Seroma (Grade 2–3)	
	OR (95% CI)	p value
Age (year)(≥ 60 or < 60)	3.020-19.811	< 0.001
BMI (kg/m ²)(≥ 25 or < 25)	5.422–38.972	< 0.001
Hypertension	1.346–10.208	0.011
Diabetes	0.061–4.295	0.537
Neoadjuvant chemotherapy	0.142–2.317	0.436
Suture type		
group 2 vs group 1	0.200-1.658	0.307
group 3 vs group 1	0.138–1.397	0.164

ME: mastectomy; BMI: body mass index.

Table 5

	Yes	No
Great impact on life of drainage	3(16.7)	15(83.3)
Willing of extension of drainage time	17(94.4)	1(5.6)

Discussion

This study showed that the same effect could be achieved as that of quilting suture by prolonging the time of drainage *in situ* around two weeks postoperatively in conventional suture group concerning to the formation of seroma in Grade 2 and 3 within one month after mastectomy with SLN or ALND. This study also showed that there was no need to prolong the drainage removal time more than two weeks; old age, high BMI and hypertension were risk factors on postoperative seroma formation, consistent with previous results from similar studies[5, 8–11].

In our previous study, we showed that conventional suture led to a high incidence of late Grade 2 and 3 seroma forming after drainage removal[7]. We tried to find a way to decrease the Grade 2 and 3 seroma in the conventional suture group. We prolonged the duration of drainage *in situ*, from the day of removal around 5–9 days to two or three weeks postoperatively. In our previous study, the timing of drainage removal was 5–9 days in both conventional and quilting suture groups. The incidences of late Grade 2 and 3 seroma were 15.1% in conventional group and 4.3% in quilting group. In this study, we removed the drainage on 13–15 days postoperatively in conventional suture group 2, and on 20–22 days in group 3. The results showed that the incidence of late Grade 2 and 3 seroma was as low as that in quilting suture group, without significant difference ($p = 0.412$). This meant that extension of drainage *in situ* could decrease the formation of Grade 2 and 3 seroma.

There were some controversies about the time of drain removal. Some studies showed that seroma did not be reduced by prolonged suction drainage of the wound, and short-time drainage of 3–6 days was safe, economical and acceptable [12, 13]. Some others showed that early removal of drainage was not beneficial and tried to find complementary solution for it [14–16]. In this study, the data showed that the removal of drainage on 13–15 days postoperatively was the suitable time point and was long enough to reduce the incidence of Grade 2 and 3 seroma. There was no need to prolong the drainage *in situ* to 20–22 days which only achieved a 1.4% reduction of incidence of late Grade 2 and 3 seroma. A study from Gupta *et al.* showed that 8-day drainage had significant advantages in reducing the number of aspiration and total aspiration volume compared to 5-day drainage, and the number of lymphoceles drained in the 5-day group was significantly higher than the 8-day group (48% vs. 28%) [17]. The incidence of 28% in the 8-day group was comparable with the results in our previous study with an incidence of 19.3% of Grade 2 and 3 seroma in the conventional group with drainage *in situ* 5–9 days (mean 7.8 days). Although the study from Gupta *et al.* did not categorize the seroma according to the severity, there were a total of 42 aspirations for the lymphoceles of 16 (28%) patients. This implied that these aspirated lymphoceles

might be Grade 2 and 3 according the criteria for adverse events classification (CTCAE) 4.0. In our opinion, the incidence 19.3% of Grade 2 and 3 seroma was quite high and aspirations of seroma were not economical benefit. This study showed that the extension of 5–7 more days of drainage was a solution to this problem, and what more was that extension to 20–22 days postoperatively was unnecessary and superfluous.

Some studies implied that long drainage time might be associated with higher surgical site infection and discomfort [14, 18–22]. In fact, not only in this study but also in our previous study, there was no significant difference of surgical site infection among these groups with various duration of drainage. In our opinion, we could avoid the surgical site infection by obeying aseptic principle during the duration of drainage *in situ*. Furthermore some meta-analyses showed that more drainages for the seroma did not increase the surgical site infection [23, 24]. Concerning to the drainage discomfort of patients, only 16.7% patients in this study thought that drainage had a great impact on their daily life, and 83.3% patients experienced minor discomfort and got used to the drainage system. Compared to the repeat visit to outpatient clinics, most patients (94.4%) would like to prolong the duration of drainage *in situ* which would not bring too much trouble to their daily life. Another reason for this was that repeat visit to outpatient clinics was costly and time-consuming. The only patient who preferred repeat visit to outpatient clinics and aspiration was a 46-year old lady and wanted to return to work without a drainage system. This was quite different from the results of Ackroyd *et al.* which showed that most of patients (81%) preferred for early drain removal, even with a high incidence of seroma (84%) [13]. For all the patients with drainage system, it was their urgent desire to remove the drainage. But for those patients who had experienced symptomatic seroma and visit outpatient repeatedly, they would be like to change their mind to keep the drainage system for longer time, as shown in our study. In a word, extension the duration of drainage *in situ* was safe and acceptable.

There are some limitations in this study. First, this was a retrospective study without randomization. There were several clinical trials have been processed to evaluate the effect of flap fixation on the formation of seroma [25, 26]. More useful information would be obtained from these studies in the near future. Second, the influence-on-life assessment was simple and subjective. Homogenized questionnaire is needed to better evaluate the impact of drainage on daily life. Third, we only assessed the impact of drainage on patients with Grade 2 and 3 seroma in group 2 and 3. Evaluation of all the patients in this study would be more convincing.

Conclusion

Prolonged timing of drainage postoperatively in patients with conventional suture could reduce the incidence of Grade 2 and 3 seroma as lower as that in quilting suture group at pectoral area within one month after mastectomy. The suitable time point of drainage removal was 13–15 days postoperatively. There was no need for extension of drainage removal to 20–22 days postoperatively.
