Abstract

Background.

The systemic inflammatory response following severe coronavirus infection (COVID-19) is associated with poor outcome. Several anti-inflammatory medications were studied in COVID-19 patients. Xanthohumol (Xn), a natural extract from hop cones, possesses strong anti-inflammatory and antioxidative properties. The aim of this study was to analyse the effect of Xn on the inflammatory response and the clinical outcome of COVID-19 patients.

Methods

Adult patients treated for acute respiratory failure (PaO$_2$/FiO$_2$ less than 150) were studied. Patients were randomized into two groups: Xn – patients receiving adjuvant treatment with Xn at a daily dose of 4.5 mg/kg body weight for 7 days, and C – controls (patients receiving placebo – NaCl 0.9%). Observations were performed at four time points: immediately after admission to the ICU and on the 3rd, 5th and 7th days of treatment. The inflammatory response was assessed based on the plasma IL-6 concentration, neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR), C-reactive protein (CRP) and D-dimer levels. The mortality rate was determined 28 days after admission to the ICU.

Results

Seventy-two patients were eligible for the study, and 50 were included in the final analysis. The mortality rate was significantly lower and the clinical course was shorter in the Xn group compared to controls (20% vs. 48%, p < 0.05, and 9 ± 3 days vs. 22 ± 8 days, p < 0.001). Treatment with Xn decreased plasma IL-6 concentration (p < 0.01), D-dimer levels (p < 0.05) and NLR (p < 0.01) more significantly compared to standard treatment.

Conclusion

Adjuvant therapy with Xn appears to be a promising anti-inflammatory treatment in COVID-19 patients.

Introduction

Since December 2019, when a new type of severe acute respiratory syndrome coronavirus (SARS-CoV-2) was described, many studies have been performed to identify an effective treatment to alleviate signs and symptoms. This infection is caused by β-coronavirus 2 (CoV-2) and is associated with multiorgan dysfunction resulting mainly from endothelial damage complicated by massive inflammatory response syndrome [1–4]. Coronavirus-induced symptoms are referred to COVID-19 disease.

Several studies on COVID-19 documented a strong relationship between the severity of the clinical condition and the degree of inflammatory response to viral infection [5–8]. Immune dysregulation is a trigger for cytokine storms. An increase in the release of inflammatory cytokines, especially interleukin-6 (IL-6), associated with T-
cell lymphopenia is correlated with poor outcome and death [5, 6, 8]. A rapid increase in the inflammatory response is associated with uncontrolled production of reactive oxygen species and free radicals, which significantly impair cellular metabolism [9, 10]. Several authors have studied the efficiency of anti-inflammatory and antioxidant treatment to reduce COVID-19-related complications and death [5, 9–17]. Interestingly, natural compounds have also been suggested as effective adjuvants in COVID-19 therapy [18, 19]. These compounds possess different anti-COVID-19 activities. Some of them compounds block IL-6 release, which could reduce the need for mechanical ventilation and thus also admission to the intensive care unit (ICU) [13–15]. Other compounds directly inhibit viral replication by binding to specific receptors [20, 21]. Interestingly, some compounds present similar chemical structures. In silico studies suggested a high efficiency of naturally occurring prenylated chalcones for the treatment against coronavirus infection [15, 22, 23].

Xanthohumol is a prenylated chalcone (Fig. 1) that can be extracted from female inflorescences of hop cones (Humulus lupus). The chemical structure of Xanthohumol (Xn) is composed of open-chain flavonoids with configured A and B aromatic rings, which are joined by three carbon – α,β-unsaturated carbonyl groups substituted by hydroxyl groups. Xanthohumol is produced in the glands of secretory hairs located in the hop cones. Increasing numbers of studies have documented the immunomodulatory properties of Xn [24–26]. Xanthohumol inhibits proinflammatory pathways via inhibition of farnesoid X receptor (FXR) activity and NF-κB-dependent inhibition of proinflammatory gene expression, such as IL-1β, IL-6, IL-8, IL-12p70, TNFα and interferon γ [23–26].

Experimental studies documented a strong effect of Xn against many DNA and RNA viruses, such as herpes simplex virus types 1 and 2, cytomegaloviruses and porcine reproductive and respiratory syndrome virus (PRRSV) [22, 25–28]. Interestingly, PRRSV infection is similar to the course of coronavirus infection with main symptoms consisting of high fever, significant morbidity and severe respiratory disease resulting in high mortality. In vivo experiments showed that the PRRSV-infected piglets treated with Xn at a dose of 20 mg/kg exhibited only moderate clinical signs and low viral loads, whereas 25 mg/kg Xn practically reduced all clinical symptoms [28]. Another experimental study documented that Xn inhibited many viral diseases, including SARS-CoV-2 and other fatal diseases caused by alpha- or beta-coronavirus [29]. Notably, Xn is safe and well tolerated in healthy humans and is available as a dietary supplement. Based on its antiviral and anti-inflammatory properties, we hypothesized that administration of Xn could improve the clinical course and outcome in critically ill COVID-19 patients requiring mechanical ventilation.

Therefore, the aim of this study was to analyse the effect of Xn supplementation on the clinical course, inflammatory response and outcome in patients admitted to the ICU due to COVID-related acute respiratory failure with an oxygenation index (PaO₂/FiO₂) less than 150.

Patients And Methods

Ethical considerations

This prospective, observational study was conducted in accordance with the Declaration of Helsinki and applicable regulatory requirements. The local Institutional Review Board and the Bioethics Committee of the Medical University in Lublin, Poland approved the protocol (KE-0254/201/2020). Written informed consent was obtained from all patients just after admission to the ICU prior to randomization. Additionally, legal representatives were informed about the main purpose of this study.
Study drug treatment

All patients were treated following current guidelines at the time of admission. After admission to the hospital, remdesivir (Veclury, Ireland) was administered at an initial dose of 200 mg/day followed by 100 mg/day for 5 to 7 days. Additionally, vitamin D3 at a dose of 4000 U per day was supplemented in all patients. Corticosteroid therapy with dexamethasone (Dexaven, GmbH Arzneimittel, Germany) at a dose of 8 mg per day for 10 days and anticoagulant therapy with endoxaparinum natricum (Clexane, Sanofi-Aventis, France) were started upon admission to the ICU. All patients received continuous infusion of insulin to maintain plasma glucose concentrations between 100 and 160 mg/dL.

Monitoring

In all patients, systolic diastolic and mean arterial blood pressures (MAP), heart rate (HR) and expiratory CO₂ tension were monitored continuously. Additionally, haemodynamic variables, such as cardiac output/index (CO/CI), stroke volume variation (SVV), systemic vascular resistance index (SVRI) and central venous pressure (CVP), were monitored using the EV 1000 platform (Edwards Lifescience, Irvine, CA, USA). Masimo Root monitor (USA) with SEDLine was used for continuous measurement of regional cerebral oxygen saturation (SrO₂), frontotemporal electroencephalography, peripheral oxygen saturation (SpO₂) with haemoglobin level and oxygen reserve index (ORI). Fluid administration with balanced crystalloids and vasopressors (norepinephrine) were titrated to obtain MAP higher than 65 mmHg.

Patients selection and inclusion criteria

This study was performed between October 2020 and January 2021. Adult patients aged 18 years or older admitted to the ICU who were treated for severe COVID-19 with acute respiratory failure (PaO₂/FiO₂ below than 150) due to bilateral and multifocal ground-glass opacities involving greater than half of the lungs were included in the study. The quantitative computed tomography (CT) with thoracic VCAR software and the parenchymal analysis option was used to assess the degree of parenchymal impairment. Patients who were treated for COVID-19 for more than one week were excluded. Other exclusion criteria were chronic renal failure, history of illness affecting the human immunologic defence system (modulated immunologic system, such as transplant patients) and/or prolonged inflammatory response such as malignancies, rheumatologic diseases and chronic inflammatory disease. Pregnant or lactating women were also excluded. Patients, who did not respond to prone ventilation strategy were screened for eligibility for extracorporeal oxygenation (ECMO) and were excluded from this study. Patients, who died within 7 days were also excluded due to uncompleted data.

Patients were randomized in a double-blind, placebo-controlled fashion into two groups using sealed envelopes. Group Xn includes patients who received extract from *Humulus lupus L* rich in Xanthohumol (Hop-RXn™, BioActive-Tech Ltd, Lublin, Poland; http://xanthohumol.com.pl/) as an adjuvant therapy, and group C includes patients who received 0.9% NaCl formed the control group. Based on pharmacokinetics and bioactivity, Xn was administered enterally three times a day every 8 hours at a dose of 1.5 mg/kg body weight (4.5 mg/kg body weight/day) for 7 days [30]. The first dose of Xn was administered within 4 hours after admission to the ICU. In the control group, 3 mL of NaCl 0.9% was administered enterally three times a day.

Biochemical analysis
Routine biochemical examination with full blood count and morphology, including erythrocyte, platelet, leukocyte, neutrophil and lymphocyte counts, serum interleukin 6 (IL-6) concentration, C-reactive protein (CRP) and D-dimers, were performed immediately before admission to the ICU and on the 3rd, 5th and 7th days of treatment. All biochemical analyses were performed at the laboratory of University Hospital No 4 in Lublin, Poland using commercial reagents. Arterial blood gas analysis was performed a minimum of 4–6 times per day using GEM 5000 (Werfen, Barcelona, Spain). The \( \text{PaO}_2/\text{FiO}_2 \) ratio was calculated as the ratio between the oxygen tension obtained from routine blood gas's analysis and the fraction of inhaled oxygen (\( \text{FiO}_2 \)). The following formulas were used for calculation of NLR and PLR:

- NLR: number of neutrophils divided by number of lymphocytes,
- PLR: the number of platelets divided by the number of lymphocytes.

**Pulmonary disease evaluation**

The ventilator settings were determined in accordance with the results of the blood gas examination and the respiratory insufficiency was assessed by calculating the \( \text{PaO}_2/\text{FiO}_2 \) ratio (\( \text{PaO}_2/\text{FiO}_2 \)). Patients with \( \text{PaO}_2/\text{FiO}_2 \) less than 100 were placed into the prone position in accordance with a local protocol [31]. A high-resolution computed tomography (CT) technique with artificial intelligence software (Thoracic VCAR software with Parenchymal Analysis, GE Healthcare, USA) was used to assess the severity and quantitatively measure lung injury. In all participants, CT was performed immediately before admission to the ICU. A control CT was performed 2–3 days after extubation or immediately after discharge from the COVID zone in the ICU.

**Study protocol, measured variables and outcomes**

Observations were performed at four time points: 1) immediately after admission to the ICU (baseline), 2) 3 days after admission to the ICU, 3) on the 5th day of treatment and 4) on the 7th day of treatment. The degree of the inflammatory response was measured by NLR, PLR, D-dimer and plasma IL-6 concentration. Primary outcomes were mortality rates, which was determined at 7 and 28 days after admission to the ICU. Secondary outcomes were the dynamics and evolution of the inflammatory parameters and the evolution of CT imaging.

**Statistical analysis**

Statistical analysis was performed using Statistica 13.1 software (StatSoft, USA). Means and standard deviations (SD) were calculated for normally distributed variables, whereas non-Gaussian distributed variables were presented as medians and inter-quartiles range. The Kolmogorov–Smirnov test was used to analyse the normality of the data distribution. Categorical variables were compared using the \( \chi^2 \) and Fisher exact tests, and Yates correction was applied. The value at ICU admission was regarded as baseline. The unpaired student's \( t \)-test was used to analyse variables with normal distribution. Nonparametric data were statistically analysed using the Wilcoxon signed-rank test and the Kruskal–Wallis test. Additionally, the Pearson test was used for analysis of any correlation in normally distributed variables, whereas Spearman's rank test was used for interpoint and intergroup comparisons for variables with a non-Gaussian distribution. Kaplan–Meier estimation was performed for survival probability analysis. A value of \( p < 0.05 \) was considered significant.

**Results**
Study population

Seventy-two adult critically ill patients treated for COVID-19 with severe respiratory failure were included in the present study. A total of 22 patients were excluded from the final analysis: 11 were excluded because informed consent could not be obtained, and 4 died within 7 days with incomplete data. Additionally, seven patients were also excluded due to incomplete data or consent withdrawal after recovery. Finally, fifty patients (18 female and 32 male) aged 22 to 83 years (mean 58 ± 17) were studied. Twenty-five patients were randomly assigned to the Xn-group and were treated with Xn, and 25 received 0.9% NaCl and were allocated to the control group. The relevant demographic data and comorbidities are presented in Table 1.

Primary endpoints
Overall mortality was 34%. Seventeen patients died between days 7 and 28 of treatment: 5 (20%) in the Xn group and 12 (48%) in the control group ($\chi^2 = 5.56, p < 0.05$ and $\chi^2$ with Yates correction = 4.25 and $p < 0.05$, Fig. 2). All patients treated with Xn who survived were discharged from the ICU to the pulmonology or rehabilitation ward and then discharged home in good clinical condition. In the control group that did not receive Xn, none of the patients were discharged directly home. These patients were discharged to another pulmonology hospital followed by another hospital, and their outcome could not be determined.

**Changes in inflammatory markers**

The mean baseline value of NLR was 20.8 ± 16 in all participants, and was comparable in both groups (21.5 ± 14.2 vs. 20.2 ± 17.6 in the Xn-treated and control groups, respectively). Treatment with Xn resulted in a near 5-fold significant reduction in NLR at day 7 compared with baseline. In contrast, no significant NLR-decrease was observed in the control group (Table 2). In patients who survived, the NLR decreased on the 3rd and 7th day of treatment with Xn and on the day 7 in the control group (Fig. 3).

The platelet-to-lymphocyte ratio decreased on the 3rd and 7th day of treatment in the Xn-group and on the 5th and 7th day in the control group (Table 2). Changes in both groups were comparable, and no significant differences were noted.

The mean baseline value of plasma IL-6 concentration was 279.1 ± 380.1 pg/mL in all patients. IL-6 levels were comparable in both groups (298.4 ± 453.5 pg/mL vs. 256.7 ± 337.5 pg/mL in Xn-treated and control groups, respectively). Treatment with Xn reduced plasma IL-6 concentrations on the 3rd and 7th days, whereas these values were reduced on the 5th and 7th days in the control group (Table 2). In patients who survived, plasma IL-6 concentration decreased on days 3, 5 and 7 in both groups. The decrease in plasma IL-6 concentration was more pronounced in the Xn group (Fig. 4).

In both groups, D-dimer levels decreased on the 3rd, 5th and 7th days; however, treatment with Xn resulted in a more pronounced reduction compared to the control group (Table 2). In patients who survived, D-dimers decreased in both studied groups, but their concentrations were significantly lower in patients treated with Xn on the 3rd and 7th days ($p < 0.05$).

** Changes in CT lung scans and gas exchanges (PaO₂/FiO₂)**

In all patients, CT examination of the lung showed massive bilateral and multifocal ground-glass opacities (Table 3). A significant improvement in CT lung scans was noted in patients treated with Xn (Fig. 5), whereas only slight improvement was noted in patients treated with placebo (Fig. 6). Additionally, mechanical ventilation was completed within 7 day in 14 Xn patients, and 6 patients required mechanical ventilation/support for more than 7 days. None of these patients required a tracheostomy. In the control group, mechanical ventilation was
completed within 7 day in only 4 patients, and 8 of them required percutaneous tracheostomy due to the necessity of prolonged mechanical ventilation for up to 14 days. PaO$_2$/FiO$_2$ decreased in both groups; however, the changes were more pronounced in the Xn-group (Table 2).

### Table 3

Evolution of lung injury measured with the high-resolution computed tomography (CT) technique combined with artificial intelligence software with percentage of the pulmonary parenchyma and affected automatic detection of pathology (emphysema, normal parenchyma, ground glass opacity and consolidation). Percentages are expressed as mean with standard deviation (SD). Baseline – CT performed immediately before admission to the ICU. ** p < 0.01, *** p < 0.001 – changes between baseline and control lung pathologies assessed by artificial intelligence software, † p < 0.05, † † † p < 0.001 – differences between lung pathologies observed in the Xn and control groups.

### Discussion

In the present study, we documented that treatment with Xn significantly reduced the severity of the inflammatory response, as reflected by the plasma IL-6 concentration and NLCR, improved outcomes and reduced the mortality rate. Additionally, Xn at a daily dose of 4.5 mg/kg body weight improved the oxygenation index and reduced the length of mechanical ventilation. The mechanism responsible for these phenomena seems to be complex and pleiotropic.

### Presumed pathophysiologic mechanisms

Xanthohumol is the most abundant prenylated flavonoid in hops. Beer is the most important dietary source of Xn and other related prenylavonoids. Concededly, the brewing process induces thermal isomerization of Xn to isoxanthohumol (IXn), but Xn can be converted into IXn in the stomach [32, 33]. An in vitro study showed that both forms can be biotransformed by human liver microsomes to glucuronides, hydroxylated metabolites, and cyclic dehydrometabolites [30, 33, 34]. The bioavailability of Xn is dose dependent and increases linearly with increasing oral dose [30]. Xn has strong antioxidant and anti-inflammatory properties and protects cells from injury induced by upregulated angiotensin-2 activation [23–26, 35, 36]. An experimental study showed that angiotensin-2 stimulates the production of reactive oxygen species (ROS) via the activation of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, and Xn and its major bioactive metabolite IXn strongly inhibit this process, preventing oxidative-related endothelial injury [35, 37]. It has been shown previously, that Xn inhibits the viral-encoded cysteine protease (main protease of CoV-2) in a dose-dependent manner [29]. Importantly, this protease is necessary for viral replication. Another reported pathomechanism is based on a reduction in the intensity of viral replication related to the inhibition of diacylglycerol acyltransferase (DGAT) [20]. Massive viral replication is associated with metabolic cell damage, and the rapid upregulation of lipid
biosynthesis, particularly triacylglycerol, plays a crucial role in this process. The last step in triacylglycerol synthesis is catalysed by DGAT, the inhibition of which reduces the availability of fuel for viral replication. Xanthohumol strongly inhibits DGAT activity in a dose-dependent manner, and its antiviral effect has been noted in cardiomyocytes and type II alveolar epithelial cells – the major portal of CoV-2 infection [20]. Interestingly, Xn also has the most potent activity, improving cell viability from all chalcones extracted from *Humulus lupus* [36]. In the present study, we observed relatively quick improvement in blood oxygenation and CT-lung imaging after 7 days of treatment with Xn. Therefore, we can speculate that the use of Xn at a dose of 4.5 mg/kg body weight may be a safe and effective adjuvant therapy in severe COVID-19 patients.

**Anti-inflammatory properties**

The therapeutic effect of Xn can also be explained by its anti-inflammatory properties. We noted a significantly lower IL-6 concentration and NLR in patients treated with Xn. Rapid and massive production of proinflammatory cytokines, particularly IL-6, is associated with the severity of COVID-19. In the present study, the plasma IL-6 concentration upon admission was 100-fold higher than normal, and the addition of Xn to the treatment regimen resulted in a rapid and significant decrease in its concentration. Several studies documented the strong anti-inflammatory properties of Xn with reduction in proinflammatory cytokines and the number of macrophages in injured tissues [24, 38, 39]. Administration of Xn reduced plasma IL-6 levels by approximately 80% [40]. An animal study showed that Xn effectively reduced tumour necrosis factor alpha (TNF-α), IL-6 and IL-1β secretion and suppressed high-mobility group box 1 protein (HMGB1) and inducible nitric oxide synthase (iNOS) expression [38]. A decrease in the production and release of proinflammatory cytokines is associated with the suppression of nuclear factor-kappa B (NF-κB), which inhibits T-cell proliferation [29, 38, 39]. Interestingly, anatomopathological examination of animal lungs revealed a significantly lower neutrophil infiltration in injured lungs, and lung damage was markedly reduced in animals treated with Xn compared to those treated with remdesivir [20, 39]. In the present study, CT-scans also showed markedly less consolidations and bilateral diffuse mixed densities of the lung in patients treated with Xn compared to controls. All our patients tolerated Xn well and none of them had adverse effects. Therefore, we suggest adding Xn as an adjuvant to standard therapy in COVID-19 patients.

The neutrophil-lymphocyte count ratio is frequently used as a marker of the severity of inflammation and outcome [41–45]. Elevated values of NLR predict poor outcome in patients treated for traumatic brain injury [41], mesenteric ischaemia [42] or sepsis [43]. Importantly, NLR has also been proposed as a sensitive marker of endothelial dysfunction following viral infection [44]. Progressive endothelial damage following viral infection, including CoV-2, induces massive glycocalyx injury, leading to endothelial inflammation with uncontrolled neutrophil activation, vasoconstriction and coagulation disorders [3, 4, 45]. Anatomopathological examination of lungs from patients with COVID-19 showed the presence of viral inclusion and massive inflammation in endothelial cells [46–48]. The virus binds to the angiotensin-converting enzyme 2 (ACE-2) receptor, displaying profound tropism for the human vascular endothelium and the lungs [47, 48]. Inflamed endothelial cells induce proinflammatory cytokine production, leading to general hyperinflammation with subsequent influx of activated monocytes, neutrophils, and other immune cells. An increase in blood neutrophils with low lymphocyte count may predict poor outcome. It has been shown that an increase in NLR above 10 is a strong predictor of fatal outcome in critically ill COVID-19 patients [48, 49].

**Endotheliopathy**
Severe COVID-19 has been linked to endotheliopathy and vasculitis, which has been documented in several studies [1–4, 50, 51]. Elevated plasma D-dimer concentrations, which are fibrin degradation fragments, is associated with an increased risk for morbidity and mortality in COVID-19 patients [52, 53]. The virus possesses a strong affinity for the vascular endothelium, leading to lymphocytic endotheliitis with infiltration of inflammatory cells around the vessels and endothelial apoptotic cell death [54]. A rapid increase in the concentration of proinflammatory cytokines, such as IL-6 and TNF-α, reduces the physiological antithrombotic and anti-inflammatory functions of endothelial cells, and triggers the procoagulopathy cascade [55]. Hence, extensive inflammation may disturb the crosstalk between the endothelium, platelets and the coagulation system, leading to the formation of clots in the microvascular circulation of several organs, especially the lungs. Xanthohumol inhibits inflammatory-induced endothelial dysregulation, exerting antiangiogenic and anti-inflammatory effects via the reduction of NF-κB activity, a well-established angiogenic and inflammatory factor [37, 38, 56]. Interestingly, an experimental study documented that Xn at a dose of 10 mg/kg body weight administered twice daily during 7 days improves blood velocity and reduces the risk of arterial thrombosis, decreasing the incidence of pulmonary embolism [57]. Additionally, treatment with Xn does not affect other coagulation factors, prothrombin time (PT), activated partial thrombin time (APTT), or thrombin time (TT), but it insignificantly inhibited platelet activation and adhesion on collagen-coated surfaces [57]. In the present study, we noted a much more profound decrease in D-dimers in the Xn-group compared to the control group. Additionally, changes in lung CT were also more pronounced in the Xn-group. Therefore, we can speculate that Xn reduces vascular damage and the formation of microarterial thrombosis; however, this hypothesis should be confirmed in further studies.

**Limitations**

Despite promising findings, our study has several limitations. First, because of the small number of patients treated with Xn the power of our analysis was significantly reduced. Second, our analysis of Xn-related anti-inflammatory effects was based on commonly assessed variables. Several experimental studies have documented that Xn reduces many circulating proinflammatory cytokines in different diseases [8, 23–26, 38, 58, 59]. Third, we did not analyse blood Xn and its metabolites concentrations. Previous studies showed that Xn is a safe and nontoxic supplementary product; however, its interaction with other anti-inflammatory medications has not been well documented. Additionally, we did not analyse an effect of Xn on blood glucose levels. Experimental studies have shown that Xn may be favourable for glucose metabolism, and treatment with Xn at a dose of 60 mg/kg body weight per day effectively reduced plasma glucose, total cholesterol and LDL-cholesterol concentrations [40, 60]. A reduction in plasma glucose concentration following Xn administration was only noted in male mice, whereas higher liver concentrations of Xn and its metabolites were found in female mice [60]. It has been well established that IL-6 affects glucose homeostasis. Increased IL-6 levels impair insulin action, whereas inhibiting IL-6 improves hepatic insulin sensitivity [61, 62]. In the present study, the blood glucose concentration was maintained with continuous insulin administration, and the dose of insulin was not analysed. Therefore, we hypothesise that Xn affected glucose metabolism via a decrease in IL-6 concentration; however, this hypothesis should be confirmed in further studies.

Fifth, oestrogen and others sex hormones activity were not monitored. Importantly, Xn presents oestrogen activity by increasing the levels of 8-prenylnaringenin, which strongly reduces the inflammatory response and proinflammatory cytokine release [60, 63, 64]. Additionally, 8-prenylnaringenin also shows anti-inflammatory and vascular-protective properties, which could have had a significant impact on our patients [64]. Sex steroids are
potent immune modulators and suppress the production of proinflammatory cytokines, such as IL-6, IL-1β and TNF-α [65]. An experimental study showed a reduction in IL-6 production following oestrogen administration, and clinical observation documented a negative correlation between plasma oestrogen concentration and lung functionality in COVID-19 patients [66, 67]. Another clinical observation documented a significantly increased mortality rate and severe respiratory failure in males compared with females [68]. Oestrogen supplementation was also associated with a decreased risk of death in postmenopausal women [69]. In the present study, the numbers of males and females were comparable in the studied group. However, only one woman died in the Xn group, and two died in the control group. Therefore, we hypothesise that the Xn-related increase in the oestrogen concentration might play a role in outcome because the limited number of patients and lack of hormone control preclude drawing such a conclusion.

In the present study, we confirmed the beneficial effects of adjuvant therapy with Xn in critically ill COVID-19 patients requiring mechanical ventilation. Based on our findings, we hypothesise that Xn may also improve the clinical course of COVID-19 in patients with only slight symptoms and may reduce the risk for developing severe respiratory failure, needing mechanical ventilation, however this hypothesis must be confirmed in further studies.

**Conclusions**

Xanthohumol appears to be a promising adjuvant treatment for COVID-19 patients with severe respiratory failure who require mechanical ventilation. Treatment with Xn improved the clinical course and reduced the severity of the inflammatory response and mortality rate. Further studies in a large cohort of patients are needed to confirm these findings.

**Abbreviations**

- ACE-2 - Angiotensin converting enzyme 2,
- ALC - Absolute Lymphocyte Count,
- APACHE II - Acute Physiology and Chronic Health Evaluation II,
- APTT - Activated Partial Thromboplastin Time,
- CoV-2 - Coronavirus-2,
- CI - Cardiac Index,
- CO - Cardiac Output,
- CRP - C-Reactive Protein,
- CT - Computed Tomography,
- DGAT - Diacylglycerol Acyltransferase,
- FXR - Farnesoid X Receptor,
Declarations

Ethical Approval and Consent to participate

This study was conducted in accordance with the Declaration of Helsinki and applicable regulatory requirements, and was approved by the Institutional Review Board and the Bioethics Committee of Medical University at Lublin, Poland (KE-0254/201/2020). Informed consent was obtained from all patients. Additionally, legal representatives were informed about the main purpose of this study.

Consent for publication
Written informed consent for publication was obtained from all patients.

**Availability of data and materials.**

The dataset used in the current publication is available from the corresponding author.

**Availability of data and materials:**

The original data can be obtained from the corresponding author.

**Competing interest:**

The authors declare no conflicts of interest.

**Funding:**

The study was supported by a scientific grant from the Medical University of Lublin, Poland (DS 352/2019). The funder had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

**Author contributions:**

Wojciech Dabrowski, Mariusz Gagos and Dorota Siwicka-Gieroba made substantial contribution to concept and design this study. Wojciech Dabrowski, Dorota Siwicka-Gieroba, Mariusz Piechota, Jan Siwiec and Andrzej Stepulak were involved in data collection, analysis, and interpretation and drafted the manuscript. Luiza Grzycka-Kowalczyk analysed and prepared CT scans. Wojciech Dabrowski, Magdalena Bielacz, Andrzej Jaroszynski and Manu LNG Malbrain were involved in the collection of references, figure preparation, data interpretation and drafted the manuscript. All authors designed the study, drafted the manuscript, and read and approved the final manuscript.

Figure 5

Sample of quantitative computed tomography (CT) of the lung with thoracic VCAR analysis in 2 patients successfully treated with Xn at a daily dose of 4.5 mg/kg body weight for severe COVID-19. Both were mechanically ventilated with FO2 1.0 in the prone position. Panel A - patient A: CT examination at baseline (A-0) was performed a few hours before the start of mechanical ventilation. The first dose of Xn 1.5 mg/kg body weight (158 mg of Xn) was administered before intubation. The baseline PaO2/FiO2 immediately after intubation was 58. After 6 days, the patient was extubated, and a control CT (A-1) was performed on the day 8. His PaO2/FiO2 was 232 on the 7th treatment day (end of the study period). This patient was transferred to the pulmonology ward and discharged at home after 32 days of treatment in good clinical condition. Panel B - patient B: CT examination at baseline (B-0) was performed just before admission to the ICU/ The first dose of Xn was administered immediately before admission. The patient was intubated within 3 hours after admission to the ICU, and mechanical ventilation in the prone position was started after intubation. His baseline PaO2/FiO2 was 52 just after intubation. The patient was extubated on the 7th day of treatment, and a control CT (B-1) was performed on the 9th day. The patient was discharged to the pulmonology ward and then discharged at home on day 35.
Figure 6

Sample of quantitative computed tomography (CT) of the lung with thoracic VCAR analysis in a patient treated with placebo (NaCl 0.9% at a dose of 3 mL administrated 3 times per day). The patient was mechanically ventilated with FO$_2$ 1.0 in the prone position. Quantitative CT was performed a few hours before the start of mechanical ventilation (C). The baseline PaO$_2$/FiO$_2$ just after intubation was 55. After 13 days, the patient was extubated, put on non-invasive ventilation (NIV). The patient was transferred to another hospital, and was finally discharged at home on day 98.
