## SUMMARY

**Background and objective:** Tuberous sclerosis (TS) is a condition whose manifestations in childhood have been extensively described, but whose presentation in adults is less well known. This study describes the clinical and genetic characteristics, therapeutic management and quality of life of a cohort of adult patients with TS. A comparative study of the characteristics of patients diagnosed in childhood and adulthood is also carried out.

**Material and methods:** This observational, retrospective, cross-sectional study included a large cohort of adult patients ( $\geq 16$  years old) followed for 5 years in a specific rare diseases unit.

**Results:** Fifty-seven patients with a diagnosis of tuberous sclerosis were included, more than 50% of whom were diagnosed as adults. The mean age of the patients was 42 years (20–86). The central nervous system was the main area affected (97%), followed by the skin (80.7%) and kidneys (73%). The most frequent genetic alteration was a mutation in the TSC2 gene (47.7%). Among patients diagnosed in adulthood, there was less neurological involvement, with less frequency of epileptic seizures (30.8% vs 60.79% of patients diagnosed in childhood) and astrocytomas (3.8% vs 53.6%), less intellectual disability (11.5% vs 71.4%) and less expressiveness of the condition. 42% of patients were treated with mTOR pathway inhibitors, and presence of an angiomyolipoma was the main indication. In a quality-of-life analysis, the means of the summary indices were below the scores of the average Spanish population: (47.42 (SD  $\pm$ 9.82) on the physical health scale, 45.61 (SD  $\pm$  7.99) on the mental health scale) versus 50 (SD  $\pm$ 10) for the general population.

**Conclusions:** Up to 50% of adult patients with TS were diagnosed in adulthood, and the condition is less severe with less frequent epileptic seizures and intellectual disability. 42% require treatment with mTOR inhibitors, in most cases due to the presence of AMLs. The quality of life of adult patients with TS is diminished compared to the general population.

**KEYWORDS:** Tuberous sclerosis, adult, quality of life, multidisciplinary unit

## ABBREVIATIONS

TS: Tuberous sclerosis  
TSC: Tuberous sclerosis complex  
AML: Angiomyolipoma  
LAM: Lymphangiomyomatosis  
SEGA: Subependymal giant cell astrocytoma  
TAND: TSC-associated neuropsychiatric disorders  
mTOR: Mammalian target of rapamycin  
SD: Standard deviation  
MR: Magnetic resonance

## INTRODUCTION

Tuberous sclerosis (TS) or tuberous sclerosis complex (TSC) is an autosomal dominant neurocutaneous disorder with high penetrance and variable expressivity, characterized by the formation of benign tumors (hamartomas) in multiple organs (brain, skin, kidneys, retina, heart and lungs).<sup>1</sup> The prevalence of TS ranges from 7 to 12 cases per 100,000 inhabitants and the incidence at birth is 1 case per 5000-10,000 newborns.<sup>2-5</sup>

Mutations in one of two tumor suppressor genes (TSC1 and TSC2) have so far been identified as the cause of TS. These genes encode two proteins (hamartin and tuberin) which form a complex, whose functions include cell growth inhibition by inhibiting mammalian target of rapamycin complex 1 (mTORC1), among other things.<sup>6,7</sup>

Diagnosis is based on genetic and/or clinical criteria established at the International Tuberous Sclerosis Complex Consensus Conference in 2012.<sup>7</sup> Patients require close monitoring to assess disease progression and the appearance of new lesions.

mTOR inhibitors have been used in recent years for the treatment of this condition. The accepted indications for these drugs are the presence of growing asymptomatic subependymal giant cell astrocytomas (SEGA), renal angiomyolipoma with lesions larger than 3 cm in diameter and growing, lymphangiomyomatosis (LAM) with moderate, severe, or rapidly progressive involvement, and epilepsy refractory to treatment.<sup>8</sup> Trials conducted so far with mTOR inhibitors have shown good effectiveness and safety.<sup>9-16</sup>

TS is a multisystem disorder in which phenotypic expression can vary over the years, with neurological and cutaneous manifestations being more prevalent in childhood, and kidney and pulmonary involvement more characteristic of adulthood. Because of this, it is necessary to ensure a structured follow-up throughout the patient's life, which will necessarily involve different specialists. The creation of multidisciplinary units to tackle the condition enables comprehensive integrated patient management.<sup>17-19</sup> These teams

should include both pediatricians and internal medicine specialists to facilitate the transition to adulthood.

TS is a condition that is usually reported in childhood, while less is known about it when it presents in adults. The objective of this study is to describe the clinical manifestations of a cohort of adult patients followed in a special multidisciplinary unit of a tertiary hospital, collecting clinical and genetic characteristics, details of therapeutic management and quality of life, and finally to carry out a comparative study of the characteristics of patients diagnosed in childhood and adulthood, as well as the evolution of patients treated with mTOR inhibitors.

## MATERIAL AND METHODS

This retrospective, observational, cross-sectional study was conducted in the Unit for Rare Diseases in Adults at the University Hospital 12 de Octubre in Madrid, Spain, and included all patients aged  $\geq 16$  years with a diagnosis or high suspicion of TS who were being followed after a consultation at the unit between September 2013, when the unit opened, and January 2019. The diagnosis of TS was made in accordance with the recommendations of the International Tuberous Sclerosis Complex Consensus Conference of 2012.<sup>7</sup>

For collection of variables, an ad hoc program was designed using the Windows Excel program. Data were collected from the electronic clinical record. Patient follow-up was in accordance with standard clinical practice, with an annual patient assessment if the condition remained stable, and every 4-6 months if receiving mTOR inhibitor treatment or if monitoring was necessary for progression of some clinical sign or symptom.

All patients were assessed on every occasion by an Internal Medicine specialist with expertise in rare diseases, and by other specialists depending on the needs of the patient. A descriptive analysis of the variables collected was carried out. Continuous variables were presented as means (with standard deviation) for normally distributed data, and as medians when they did not follow a normal distribution; categorical variables were presented as frequencies (n) or percentages (%). 2 x 2 or n x 2 contingency tables were constructed to study frequency distributions.

Qualitative variables were compared using the chi-squared test, or the Fisher's exact test. Inferences for continuous variables were estimated after first applying the Student's t-test.

The SF-36 questionnaire was used to evaluate quality of life. The questionnaire manual (Spanish Version of SF-36v2™ Health Survey© 1996, 2000 adapted by J. Alonso et al., 2003) was used to score the eight scales of the questionnaire and calculate the two physical and mental summary measures. Missing values for any of the items were imputed, provided that 50% of all items on the scale in question had been answered. Pearson's correlation coefficient was used to study correlations between the eight scales of the questionnaire, and the two summary measures. The Student's t-test (two groups) or ANOVA (more than two groups) were used to compare scores between different groups.

All analyses were carried out using SPSS version 21.0 (SPSS Inc. Chicago, IL, USA). Values of  $p < 0.05$  were considered statistically significant.

## RESULTS

### General aspects

A total of 61 patients were assessed up to January 2019, 4 of whom were excluded because they did not meet the definitive criteria. The final cohort studied comprised 57 patients (27 men (47.4%) and 30 women (52.6%)) with a mean age of 42 years (20-86). The demographic characteristics of the population studied are listed in Table 1. With respect to the clinical diagnostic criteria for tuberous sclerosis (Table 2), half of the patients (50.8%) satisfied between 3 and 5 of the major criteria, and 15.8% of the patients more than 7 criteria. With respect to the minor criteria, 52.6% had none, 35.1% had one, and 12.3% two minor criteria.

### Description of the clinical characteristics of the adult patients with TS

The predominant clinical manifestations in our cohort are listed in table 3. The main clinical involvement was neurological (97%), followed by dermatological (80.7%) and renal (73.7%).

### **Neurological manifestations**

The most frequent neurological manifestations were cortical tubers and subependymal nodules, with a prevalence of 86% and 56% respectively. SEGA was diagnosed in 29.8% of patients. Of the 17 patients with SEGA, 8 had undergone surgery in childhood.

Cranial MRI was performed in 89.5% of the patients. In 49.1% (28 patients), the lesions remained stable in follow-up tests, and in the rest, there were no previous test results with which to compare their evolution.

Thirty-eight (66.6%) of the patients suffered epileptic seizures (Table 4). In twenty-six of these (68.4%), the episodes were controlled and there had been no new ones in the past year; in 13.2%, the seizures were controlled but there had been some seizure in the past year, and in 18.4% of patients, the seizures were uncontrolled. Of the patients with epilepsy, 36.8% presented as generalized tonic-clonic seizures, 21.1% as absence seizures. The rest of the cases had different types of seizure, or it was not possible to

obtain the information. The mean number of antiepileptic drugs prescribed to epilepsy patients was 1.82 (SD  $\pm$  1.27), with a range between 0 and 5.

With regard to cognitive alterations, 31 patients (54.4%) had no intellectual disability, 24.6% had mild disability, 8.8% moderate, and 12.3% of the patients were classified as severely disabled. Patients with the worst control of epileptic seizures were also observed to be those with the greatest intellectual disability. Of the patients without disability, 54.8% were seizure free and only 3.2% had uncontrolled seizures, which contrasts with the severely disabled patients, 57.1% of whom had uncontrolled seizures and none was seizure free. These differences were statistically significant  $p < 0.0001$ .

### **Renal manifestations**

Cysts were found in 43.8% of patients and angiomyolipomas in 61.4%. Some 24.5% of patients had arterial hypertension and 12.3% showed deteriorating kidney function. Among the patients with renal AMLs, 2 patients (5.7%) had a single AML, 5 patients (14.3%) had several (2-3) and 28 patients (80%) had multiple AMLs ( $>3$ ). In four patients, the size of the AML was between 3 and 5 cm, in another four, between 5-8 cm, in thirteen, more than 8 cm, and in 14 patients  $<3$ cm. Bilateral renal AMLs were found in 94.3% of patients. The most frequent clinical manifestations were deterioration of renal function in seven patients, spontaneous bleeding in two patients and hematuria in another patient.

Among the treatments used for patients with AML, mTOR inhibitors were the most frequent (in 57% of cases). After the histories and clinical data of the 35 patients with AMLs were reviewed, it was found that, prior to the start of follow-up in our unit and before use of mTOR inhibitors, 5 patients (14.3%) had undergone nephrectomies, six (17.1%) one or several embolizations, and 4 patients (11.4%) had required kidney transplants due to end-stage kidney disease.

### **Pulmonary manifestations**

Lymphangiomyomatosis (LAM) was found in 16 patients (28.1%), all of them women. Most patients were asymptomatic. The main clinical pulmonary manifestation was a pneumothorax in five patients (31.3%). Of the patients with LAM, ten (62.5%) were classified as mild, five (31.3%) as moderate, and one (6.3%) as severe.

## **Cutaneous manifestations**

The most common cutaneous manifestation was facial angiofibromas (70.2% of patients with TS). Also reported were hypomelanotic macules, in 43.9% of patients, fibrous cephalic plaques in 1.8%, shagreen patches in 22.8%, confetti skin lesions in 10.5%, periungual fibromas in 43.9%, intraoral fibromas in 8.8% and dental enamel lesions in 3.5%.

## **Other manifestations**

Cardiac involvement was detected in 16 patients (33.3% of those who had specific studies) in the form of cardiac rhabdomyomas, all of whom already presented residual tumors. No associated arrhythmias were reported. Retinal hamartomas were described in 10 (17.5%) of the patients, taking into account that 54.4% of the patients had never been assessed by an ophthalmologist. No cases of secondary visual alterations were found.

## **Description of the genetic characteristics of adult patients with TS**

Genetic screening, involving complete sequencing of exonic and intronic regions of TSC1 and TSC2 genes and multiplex-ligation probe amplification (MLPA) analysis, was conducted in 77.2% of the patients: eleven (25%) patients had a mutation in the TSC1 gene, 21 (47.7%) in the TSC2 gene, 8 presented mutations of uncertain significance, and in 4 patients (9%), no variants that could be considered potentially pathogenic were detected.

With respect to the clinical manifestations, patients with a proven genetic predisposition had greater renal involvement and more AMLs. However, no differences of neurological involvement were seen in the form of seizures, nor in terms of pulmonary, cutaneous, cardiac or ophthalmological involvement.

When the manifestations of patients were examined according to whether they had mutations in the TSC1 or TSC2 gene, the only statistically significant differences seen were seen in the appearance of more renal AMLs in patients with the TSC2 mutation, but not in other types of involvement. At the same time, only patients with mutations in TSC2 required treatment with mTOR inhibitors.

### **Differences in clinical manifestations according to age at diagnosis**

Twenty-eight patients (49.12%) were diagnosed in childhood ( $\leq 16$  years old) and 26 (45.6%) in adulthood. Those who were diagnosed in childhood had more major diagnostic criteria ( $5.82 \pm 1.517$ ) than those who received their diagnosis in adulthood ( $3.08 \pm 1.623$ ) ( $p < 0.0001$ ).

The clinical presentation at diagnosis was epilepsy in 85.7% of patients diagnosed in childhood. Of the patients diagnosed in adulthood, 50% were related to kidney and skin affectations, and the other 50% were diagnosed following screening for TS as a result of having an affected family member.

With regard to genetic predisposition, patients diagnosed in childhood more frequently presented mutations in the TSC2 gene (43%) versus 14% in TSC1. Among those diagnosed in adulthood, 27% had mutations in TSC1, 53.8% mutations in TSC2, with 42.8% of the latter mutations being of uncertain significance.

Patients diagnosed in childhood had greater neurological involvement at all levels: in the form of seizures, the presence of subependymal nodules and astrocytomas, although this difference was not found in cortical dysplasia. Patients diagnosed as children also has greater intellectual disability, which was practically non-existent in patients diagnosed as adults. Renal involvement was more frequent and severe in patients diagnosed in childhood, who also had more dermatological and cardiac involvement, although no differences were found at the pulmonary or ophthalmological level.

(Table 5).

The need for treatment with mTOR inhibitors was higher among patients diagnosed in childhood compared to those diagnosed as adults (67.9% vs 15.4%;  $p < 0.0001$ ). Four out of 26 patients diagnosed in adulthood received treatment with an mTOR inhibitor, and in all 4 patients, the indication for treatment was the presence of renal AMLs.

### **Description of patients receiving treatment with mTOR inhibitors**

Treatment with mTOR inhibitors was prescribed in 24 patients (42.1%). Indications for starting treatment were epilepsy in 3 patients (5.3%), SEGA in one patient (1.8%) and renal AML in 20 patients (35.1%).

The patient being treated for SEGA remained stable throughout the 5 years of treatment. The brain lesion remained stable (without the need for surgery), as did the epileptic seizures and renal AMLs that he also presented.

Two of the 3 patients with an indication for epileptic seizures were controlled, and treatment was maintained for 6 and 8 years. In the third patient, treatment was suspended due to lack of effectiveness.

In 10 of the patients treated for renal AMLs, the lesions remained stable over time and in 4 patients, they decreased in size.

The mean treatment duration was 5 years; four patients were treated for more than 8 years. The drug had to be suspended during treatment in 7 patients (29.1%) due to side effects, in 4 patients (16.6%) prior to surgery, and due to lack of effectiveness in one (4.16%) patient. It was later reintroduced in 9 of these patients and was subsequently well tolerated. Side effects were reported in 16 patients (66.6%), the most frequent being stomatitis (9 patients) which was controlled with medication in all but one case, which required a temporary suspension.

The dose also had to be lowered in 3 patients due to a dry cough at night with no evidence of pneumonitis, which improved the symptoms. 90% of the patients presented dyslipidemia, which made it necessary to use statins, and 3 presented mild hypophosphatemia that did not require treatment. Weight loss (about 5 kg) and prolonged periods without menstruation were common in women. Most showed evidence of improvement in cutaneous angiofibromas, and no major infections were described. All patients had previously been screened for TB, HBV, HCV and appropriate vaccinations. No other major drug-related side effects were described.

### **Quality-of-life analysis**

A quality-of-life assessment was conducted with 49 patients using the SF-36 questionnaire. Means and standard deviation were calculated for each of the SF-36 subscales and two summary measures (a physical health summary index (PSI) and a mental health summary index (MSI)). Subscale values ranged from 0 to 100, with higher scores corresponding to a better state of health. Mean scores of more than 70 points were obtained for the physical functioning, physical role, body pain, social functioning and emotional role scales. The results were worse on the general health (the worst affected), vitality and mental health scales.

The summary indexes are standardized and provide a direct interpretation of the scores relative to the general Spanish population, which has a mean of 50 and SD  $\pm 10$ .

The physical and mental summary indices were calculated, giving mean scores of 47.42 (SD  $\pm 9.82$ ) on the physical scale, and 45.61 (SD  $\pm 7.99$ ) on the mental scale, both below the population average.

The quality-of-life scores of the patients in our cohort were compared with quality-of-life results published for the general Spanish population. Quality of life in our cohort was observed to be significantly decreased relative to the general population on the scales for general health (56.97 vs 68.3  $p=0.0194$ ), general vitality (58.36 vs 66.9  $p=0.0221$ ), social functioning (80.35 vs 90.1  $p=0.0385$ ) and mental health (65.46 vs 73.3  $p = 0.0216$ ).

The clinical manifestations with the greatest effect on quality of life were evaluated (Table 6). The neurocognitive commitment, and hence the presence of epileptic seizures, was found to impair quality of life most, particularly in the physical component, as well as the presence of astrocytoma.

In patient subgroups that did not present clinical manifestations, the values of the physical and mental components fell within the range of the Spanish average, but decreased as the condition worsened (Table 6)

A statistically significant difference was observed in the mental health component between patients diagnosed in childhood and those diagnosed in adulthood (Table 6).

Finally, the influence of mTOR inhibitors on quality of life was analyzed, and no statistically significant differences in the mental or physical health components were found between those receiving treatment and those who were not.

## **DISCUSSION**

Tuberous sclerosis is a complex disorder with multiple organ involvement and low prevalence, with such a broad spread of cases that it is difficult to conduct studies in this population. This article describes the largest Spanish cohort of adult patients with tuberous sclerosis, which is a little described clinical condition, given the tendency to describe cohorts of child patients. It also compares the clinical characteristics of patients diagnosed in childhood versus adulthood, and explores in greater depth the parameter of quality of life, which is an important variable when dealing with chronic conditions.<sup>20-22</sup> The data collected show that practically half the patients being followed in our series (45.6%) were diagnosed as adults; neurological involvement in the form of epilepsy was

most frequently found in those diagnosed in childhood, while in adults, cortical dysplasia, cutaneous lesions and renal involvement predominated. Patients with onset of symptoms in adulthood present a mild form of the condition, with less intellectual disability and less frequency of epileptic seizures. This difference may be due to the genetic involvement,<sup>18,23</sup> with TSC2 predominating among those diagnosed in childhood.<sup>24</sup> Also worthy of note is the presence of a significantly higher number of renal AMLs in patients with TSC2 compared to TSC1, which coincides with the literature where the presence of TSC2 is reported to be of greater severity. We found the same phenomenon in the use of mTOR inhibitors, in which only patients with TSC2 were on mTOR inhibitors, whereas none of the patients with TSC1 would have required them.<sup>24</sup> Those diagnosed in childhood are also in greater need of this treatment and have a worse quality of life.

Genetic tests were conducted on 77,2% of the patients. This figure is higher than that found in other studies, such as the TOSCA (43.1%),<sup>25,26</sup> and may be due to the fact that our unit is multidisciplinary, with centralized patient assessment and uniform tests.

With respect to some of the typical clinical characteristics, we would like to highlight especially the differences found in epilepsy and cardiac rhabdomyoma; epilepsy was less prevalent in this study than has been reported elsewhere, 66.6% versus 75-90%.<sup>25,27-29</sup> This could be related to the fact that this symptom is common in children, but less so in patients diagnosed in adulthood, which was 45.6% of our population. We found cardiac rhabdomyoma in 28% of patients in our cohort, a lower percentage than described in other series, which was expected, since this is a tumor that decreases naturally with age.<sup>30</sup>

Treatment with mTOR inhibitors has been available for this condition for the last decade. The criteria for treatment were stipulated at the International TSC Consensus Conference of 2012, and refractory epilepsy was added later.<sup>8,12,13</sup> In comparison with other studies, the absolute number of patients in our cohort being treated with mTOR inhibitors was relatively small; nevertheless, 42.1% of patients in our series were receiving treatment with them, with a good safety profile.

A distinctive feature of our study is that it assesses the quality of life of adults with the condition across both physical and mental health components. As in other series, we found that quality of life was impaired in patients with TS, regardless of whether or not there was epilepsy or other cognitive disabilities.<sup>18,20,22</sup> The psychosocial aspect was the most affected, but there are significant differences in all domains of the SF-36 between patients with TS and the general population. This may suggest the need for psychosocial

counselling, both for patients and their families. We found that the quality of life of these patients was comparable to that of the general population over 60 years old.<sup>31,32</sup>

The limitations of this study are that patients come from a single center, the number of patients in the sample is small in absolute terms, and it is a retrospective study.

Despite these limitations, we highlight as strengths that the number of patients is large for a condition that is relatively rare, and that it was conducted at a referral center with experience of the pathology. In addition, it contributes a novel view from the point of view of assessment of adults, treatment, and quality of life.

## **CONCLUSIONS**

TS patients diagnosed in adulthood have a milder form of disease presentation, with less need for treatment and less deterioration in quality of life. Treatment with mTOR inhibitors achieves stability of lesions in most patients, with a low percentage of serious adverse effects.

The quality of life of patients with TS is lower than that of the general Spanish population.

**Table 1 Demographic data**

Demographic data ( <i>N</i> =57)	
Age at diagnosis, n (%)	
Adult	26 (45.6%)
Childhood	28 (49.12%)
Sex, n (%)	
Woman	30 (52.6%)
Man	27 (47.4%)
Mean age	41.96 (SD ± 14.4)
Reason for referral	
Multidisciplinary consultation	40 (70.2%)
Affected family member	13 (22.8%)
Transition to adulthood	4 (7%)
Family affected	22 (38.59%)
Genetic study, n (%)	44 (77.2%)
No mutation	4 (9%)
TSC1	11 (25%)
TSC2	21 (47.7%)
Mutation of uncertain significance	8 (18.2%)

**Table 2 Diagnostic criteria**

<b>Genetic</b>	Identification of pathogenic mutations of TSC1 or TSC2 in DNA from healthy tissue is sufficient to establish a definitive diagnosis of tuberous sclerosis complex.	
<b>Clinical</b>	<b><u>Major</u></b>	<b><u>Minor</u></b>
	Hypomelanotic macules ( $\geq 3$ , at least 5mm in diameter) Angiofibromas ( $\geq 3$ ) or fibrous cephalic plaque Ungual fibromas ( $\geq 2$ ) Shagreen patch Multiple retinal hamartomas Cortical dysplasia * Subependymal nodules Subependymal giant cell astrocytoma Cardiac rhabdomyomas Lymphangiomyomatosis (LAM) ** Angiomyolipoma ( $\geq 2$ )**	Confetti-like skin lesions Pitted teeth ( $>3$ ) Intraoral fibromas Retinal achromic patch Multiple renal cysts Extra-renal hamartomas
Definitive diagnosis:	2 major criteria or 1 major criterion + $\geq 2$ minor criteria	
Possible diagnosis	1 major criterion or $\geq 2$ minor criteria	

\*Includes tubers and cerebral white-matter radial migration lines

\*\* LAM and angiomyolipomas on their own without other alterations do not meet the criteria

**Table 3 Clinical manifestations**

Clinical manifestations	
Neurological	
Cortical dysplasia	49 (86%)
Epileptic seizures	38 (66.6%)
Subependymal nodule	32 (56.1%)
SEGA	17 (29.8%)
