Abstract

Background and purpose: Alcohol-induced osteonecrosis of the femoral head (ONFH) is a complex and heterogeneous disease. Genetic factors and epigenetic modifications are one of the pathogenesis of the disease. However, the influence of epigenetic factors on the disease has not been systematically studied. Our research aims to determine the methylation changes of alcohol-induced ONFH.

Methods An analytical cross-sectional study of a Chinese male population (50 lung cancer patients and 50 controls). The EpiTYPER of the Sequenom MassARRAY platform was used to detect the DNA methylation status of 132 Cytosine-phosphate-Guanine (CpG) sites in the OPG/RANKL/RANK gene promoter region.

Results: In the whole study group Chi-square test was used to analyze the methylation rate between the two groups, and six CpG sites were found to be different, among which OPG1_CpG_2, OPG3_CpG_4, RANK1_CpG_6, RANK3_CpG_10, RANKL2_CpG_21, and RANKL2_CpG_46 in the case group were higher than those in the control group, while OPG4_CpG_2 was lower than that in the control group. Our results showed that 146 CpG sites were measured, of which 32 were undetectable, and of the remaining 114 methylation sites, methylation levels were different in 23 CpG sites in patients with alcohol-induced ONFH compared to healthy controls. Receiver operator characteristic (ROC) curve analysis demonstrated the methylation levels of OPG/RANKL/RANK could efficiently predict the existence of alcohol-induced ONFH.

Conclusion: Our study of Chinese men suggests that several CpG sites in the OPG/RANKL/RANK gene in peripheral blood leukocytes of patients with alcohol-induced ONFH are in abnormal methylation state (hypermethylation tended to be more frequent).

1. Introduction

The reports of alcohol-induced ONFH at home and abroad are gradually increasing. Femoral head necrosis is a serious concomitant widely recognized in clinical practice Disease, high disability rate, and seriously affect the physical and mental health of patients. In China, long-term excessive alcohol intake is one of the common causes of non-traumatic femoral head necrosis[1]. The pathogenesis is currently unclear, and studies have shown that the genome Changes in epigenetics are closely related to its occurrence and development, including genetic polymorphism and methylation changes.

Ethanol can destroy bone homeostasis, which is the root cause of femoral head necrosis. Ethanol can not only directly inhibit the proliferation and differentiation of bone-forming cells, and promote their apoptosis, but also induce their precursor cells to tend to differentiate into adipocytes, and aggravate the imbalance of bone homeostasis. Studies have found that the proliferative activity of bone marrow mesenchymal stem cells (BMSC) derived from the proximal femoral shaft of patients with alcoholic femoral head necrosis decreased[2].

Bone tissue cells are one of the most active cells in the human body. Osteoblasts and osteoclasts in the human body maintain a stable relationship and maintain bone metabolism. In the process of human bone remodeling, osteoclasts are the "initiators" of bone remodeling, and osteoblasts are the "mediators" of bone remodeling. The nuclear factor κ B receptor raises the activator of NF ligand (RANKL) is the key to the coupling of bone cell osteogenesis and bone resorption. In 1997, different researchers discovered new members of the tumor necrosis factor receptor and ligand superfamily: osteoprotegerin (OPG), RANKL, and receptor activator of NF- κ B, (RANK)[3]. Subsequently, a number of studies have confirmed that OPG, RANK, and RANKL can regulate the differentiation and development of osteoclasts and affect their functions. RANKL binds to RANK on the surface of osteoclasts to promote the differentiation and activation of osteoclasts and inhibit their apoptosis. Osteostatin prevents the binding of RANKL to RANK, thus preventing the activation of osteoclasts, inhibiting the function of osteoclasts, reducing bone absorption, and playing a negative regulatory role[4–6].

Long-term excessive alcohol intake can make the ratio of OPG/RANK/RANKL unbalanced, causing loss of bone mass, causing bone tissue metabolism disorders; it may also cause changes in the intima of the femoral head nourishing artery vascular wall, accelerating the hardening of the vascular wall. Accelerate the formation of blood clots; it can make a series of changes in the body's immune system, and the OPG/RANK/RANKL system can also produce an immune response to accelerate the occurrence of femoral head necrosis.

The so-called epigenetics refers to the genetic information contained in the structure of chromosomes, not the DNA sequence. The main form of epigenetic information stored in mammalian cells is DNA methylation. DNA methylation is an epigenetic DNA modification catalyzed by DNA methyltransferase 1 (DNMT1). Gene expression can be epigenetically regulated by changes in DNA methylation. In particular, site-specific DNA methylation changes in cytosine-phosphate-guanine (CpG) The small islands surrounding the 5'-untranslated region (5'-UTR) of genes, including the hypomethylation and hypermethylation of genes, may be the key promoters of disease progression. Almost all DNA methylation occurs in the CpG doublet. The clustered CpG regions are called CpG islands, which are common in the promoter region of genes and are switches that regulate gene expression[7, 8].

Research on the relationship between the level of methylation in CpG-rich regions and diseases has been ongoing. There are more and more experimental evidences about the potential diagnostic and therapeutic effects of methylation on tumor diseases and metabolic bone diseases. However, little is known about the DNA methylation status of OPG/RANKL/RANK genes in femoral head necrosis. Our aim was to study the changes in CpG island methylation of these gene in patients with alcohol-induced ONFH.

2. Materials And Methods

2.1. Study Participants.

From 2018 to 2020, a total of 100 subjects including 50 consecutive recruited alcohol-induced ONFH and 50 healthy controls at the Second Affiliated Hospital of Inner Mongolia Medical University. The control is based on the physical examination enrollment group, without alcohol-induced ONFH or other related diseases. This study was approved by the Hospital Ethics Committee. Informed consent of all participants.

2.2. Inclusion and exclusion criteria

All patients were diagnosed with alcohol-induced ONFH in accordance with the relevant standards established by the International Bone Circulation Research Association. The patients in our study met the following criteria: patients had an alcohol intake of pure ethanol & 400 ml/week (320 g/week, any type of alcoholic beverage) for more than 6 months and a diagnosis of ONFH within 1 year; Meet imaging criteria for the diagnosis and staging of alcohol-induced ONFH. Exclusion criteria are that patients should not have direct trauma and other risk factors (such as a history of corticosteroid use, familial inherited diseases and other major diseases). The healthy control group is defined according to the following criteria: No symptoms of hip-joint disease, no history of thromboembolism. People with severe chronic diseases and other significant family genetic diseases will be excluded.

2.3 DNA Isolation

Blood samples were taken in EDTA tubes and centrifuged at 2000 rpm for 10 minutes. Blood samples are stored at -80°C for future experiments. Genomic DNA was extracted from whole blood of steroid-induced ONFH patients and healthy controls, using the GoldMag-Mini Purification Kit (GoldMag Co. Ltd. Xian City, China).

2.4 Primer Design and PCR Amplification

We obtained the information of OPG/RANKL/RANK from the UCSC genome database (<http://genome.ucsc.edu>). The PCR primers for OPG/RANKL/RANK amplicon sequences (Table 1) were designed with the online tool “epidesigner” (<http://www.epidesigner.com>).

Table 1
Characteristics of the participants

Variable (s)	Case (n = 50)	Control (n = 50)	<i>p</i> value
Sex (N)			
Female	0	0	
Male	50	50	
Age, years (mean ± SD)	42.62 ± 10.46	42.76 ± 11.19	0.949
Clinical stages

Stage III	15		
Stage IV	15		
SD = standard deviation;			
<i>p</i> ≤ 0.05 indicates statistical significance;			
<i>p</i> value was calculated by Independent samples <i>t</i> test.			

2.5 DNA methylation analysis

MassARRAY EpiTyper DNA methylation quantitative technology was used to detect the methylation degree of OPG/RANKL/RANK gene promoter in each specimen. The MassARRAY EpiTyper DNA platform combines base-specific digestion (molecular cleavage) and MALDI-TOF detection principles to realize multiple CpG analysis and detection. Unmethylated cytosine (C) is converted to uracil (U), while methylated cytosine is not affected. Therefore, sulfite treatment will produce methylation-specific sequence changes. Then use the T7-promoter on the 5' end. The primers are used for PCR amplification. After the product is subjected to a base-specific enzyme digestion reaction, the size and molecular weight of the DNA fragments depend on the base changes after sulfite treatment. Flight mass spectrometry can measure the molecular weight of each fragment. The supporting software EpiTYPER Automatically report the degree of methylation of each corresponding fragment[9].

2.5 Statistical analysis

SPSS statistics 20.0 (SPSS, Chicago, IL) was used for statistical analysis of the data.

The normality of the methylation horizontal distribution was assessed by the Kolmogorov-Smirnoff test. Chi-square test was used to analyze normal distribution data, and non-normal distribution data were analyzed by non-parametric test. The probability of methylation was analyzed using *t*' test. We also

evaluated the methylation level of OPG/RANKL/RANK by ROC curve as a predictive biomarker, and evaluated its recognition ability by calculating the area under curve (AUC).

In general, a useless test has an AUC of 0.5, while an ideal test (one with zero false negatives and zero false positives) has an AUC of 1.0. For all statistical analyses, differences were considered to be statistically significant if the P-value was less than 0.05.

3. Result

A total of 100 people participated in this study of 50 patients and 50 healthy controls. The mean ages were 42.62 ± 10.46 years for the cases and 42.76 ± 11.19 years for the controls. The information of the alcohol-induced ONFH patients and healthy participants were shown in Table 2. There were no statistically significant differences in mean age, sex between cases and controls.

A major advantage of blood based DNA methylation is that blood samples are readily available to investigate DNA methylation in patients with femoral head necrosis. This research uses MassARRAY

EpiTYPER mass spectrometer analysis technology platform, which has the characteristics of high throughput, high accuracy and high sensitivity. It can not only analyze multiple CpG sites of multiple genes, but also quantitatively detect each of the single genes. CpG units (with methylation Rate to quantify the degree of methylation of each CpG unit). When the methylation value is greater than or equal to 0.05 in probability analysis, it is considered that methylation occurs at this site; when the methylation value is less than 0.05, it is considered that no methylation occurs. Relationship between OPG/RANKL/RANK DNA methylation rate and alcohol-induced ONFH in Table 3. Chi-square test was used to analyze the methylation rate between the two groups, and six CpG sites were found to be different, among which OPG1_CpG_2, OPG3_CpG_4, RANK1_CpG_6, RANK3_CpG_10, RANKL2_CpG_21, and RANKL2_CpG_46 in the case group were higher than those in the control group, while OPG4_CpG_2 was lower than that in the control group.

Our results showed that 146 CpG sites were measured, of which 32 were undetectable, and of the remaining 114 methylation sites, methylation levels were different in 23 CpG sites in patients with alcohol-induced femur head necrosis compared to healthy controls (Table 4, Table 5 and Fig. 1). T 'test was used to test the methylation level between the cases and the control group that did not meet the normal distribution (Table 5), and non-parametric test was used to test the methylation level that did not meet the normal distribution (Table 4). Except that RANK3_CpG_5, OPG4_CpG_2, RANK1_CpG_33, RANK2_CpG_7.8, RANK2_CpG_35 locus in the control group was higher than that in the case group, the methylation level of the other 18 sites was lower than that of patients with alcohol-induced ONFH.

In order to evaluate the potential value of OPG / RANKL / RANK DNA methylation in alcoholic femoral head necrosis, we analyzed and evaluated all methylation sites and the average methylation level. ROC curves were plotted. The capacity of discrimination was assessed by calculating the AUC. The maximum area under the curve value reached 0.736 ($p=0.001$), and 4 The area under the curve value of each CpG site is greater than 0.700, indicating that OPG / RANKL / RANK methylation has a higher predictive value in alcoholic femoral head necrosis (Fig. 2).

4. Discussion

The onset of alcohol-induced ONFH is very complicated, and the exact mechanism is currently unclear, and there is a lack of effective prevention and treatment methods in clinic [10]. Although in recent years, prosthesis replacement can finally solve the problem of patients' activities, it also greatly increases the individual and social medical costs and the corresponding complications caused by prosthesis replacement. Some scholars believe that the onset of femoral head necrosis is a multifactorial and complex process. This means that in addition to environmental factors, genetic factors also play an important role in the pathogenesis. However, to date, the DNA polymorphisms identified in GWAS explain less than 10% of the genetic risk, which indicates that the pathogenesis of these diseases also involves other factors, especially epigenetic mechanisms [11]. Epigenetics is a bridge connecting environmental factors and gene interaction. Environmental factors mainly regulate the transcriptional expression activity of target genes through histone modification mechanisms such as DNA methylation and acetylation, so as not to damage the integrity of the genome. Make appropriate interpretation of genomic information to adapt to environmental changes [12].

OPG, RANK and RANKL are closely related to bone metabolism. OPG can specifically bind to RANKL, inhibit osteoclast precursor cell differentiation and bone resorption of mature osteoclasts, and induce osteoclast apoptosis, thereby inhibiting osteoclast-mediated bone resorption. RANK is a receptor for RANKL. The specific binding of the two can stimulate osteoclast precursor cell differentiation, activate mature osteoclasts, prevent osteoclast apoptosis and prolong their lifespan, and promote bone resorption [13, 14, 15]. The relative concentration of RANKL and OPG in bone is considered to be an important determinant of bone mass and strength, and inhibition of RANKL/RANK signaling has become

a therapeutic target for diseases characterized by femoral head necrosis and other increased bone resorption[16, 17]. Epigenetic mechanisms are important for osteoclast differentiation[18]. Therefore, the study of OPG, RANK and RANKL gene expression regulatory factors is very important for the study of bone metabolism.

Delgado [19] found the methylation of RANKL and OPG genes in human bone tissue, and confirmed that 5-aza-dC could inhibit the methylation of cell DNA, reduce the methylation of RANKL and OPG, and increase the expression of RANKL and OPG. Therefore, the methylation levels of OPG, RANK and RANKL genes can reflect the protein synthesis level to a certain extent, and play an important role in the regulation of bone metabolism balance. Therefore, we speculated that the changes of OPG, RANK and RANKL protein levels in patients with alcoholic femoral head necrosis might be related to the methylation level of related genes, which has certain guiding significance for the further study of epigenetic pathogenesis of femoral head necrosis.

Kitazawa [20] on mouse bone marrow stromal cell line was studied, and found that the differentiation of mesenchymal cells exist RANKL gene methylation phenomenon, RANKL gene transcription start site around the CpG methylation, can silence gene promoter activity, thus inhibiting the expression of RANKL gene, regulating differentiation of bone marrow stromal cells polymorphism, influence of osteoblast differentiation. Further experimental studies have shown that RANKL gene promoter TATA-box in the upper reaches of a single CpG loci of methylation can regulate cell and tissue specificity RANKL expression, thus affecting the osteoclast differentiation[21].

In a recent study in China, 32 CpG sites in the RANKL promoter island were found to be highly demethylated in the osteoporosis group compared to healthy controls. The OPG promoter was hypomethylated in both cases and controls, but the levels were much higher in osteoporosis patients[22]. In a recent study, genome-wide DNA methylation was performed on hip cartilage in ONFH patients. Furthermore, the accuracy of DNA methylation profile data and protein expression level of ONFH candidate differential methylated genes for cartilage injury of hip joint was further verified[23].

In this study, we aimed to conduct a case-control study to study the methylation of OPG/RANKL/RANK gene in patients with femoral head necrosis and healthy controls. Using the quantitative analysis method of peripheral blood DNA, that is, the MassARRAY EpiTYPER method, to find meaningful blood-borne femoral head necrosis early detection biomarkers. We found that hypermethylation of the OPG/RANKL/RANK gene was more common in patients with alcohol-induced ONFH. However, we cannot determine whether changes in methylation levels are a cause or a consequence of alcohol-induced ONFH. However, it also provides evidence that DNA methylation may lead to ONFH. Therefore, the change of DNA methylation level in OPG/RANKL/RANK may be helpful for the detection of alcohol-induced ONFH.

The current research has certain limitations. Due to the relatively small number of participants, its statistical capabilities are limited. Retrospective or cross-sectional design does not allow us to determine that the observed correlation between changes in methylation status and femoral head necrosis is causal. In this study, the match between cases and age, gender, and race controls was insufficient to rule

out potential confounding factors. Since gene expression is influenced and regulated by many factors in the process of translation, transcription and protein synthesis, to assess the potential causal relationship between changes in CpG site methylation levels in the OPG/RANKL/RANK system and alcohol-induced ONFH, the role of DNA methylation in bone metabolism needs to be further studied and verified by large sample experiments.

5. Conclusion

DNA methylation changes under environmental stress and is gradually recognized as the cause and regulator of human disease. To date, no epigenomic correlation studies have been conducted to investigate the role of OPG/RANKL/RANK gene methylation in the development of alcohol-induced ONFH. In order to investigate the methylation level of OPG/RANKL/RANK gene, we used peripheral blood DNA from patients with alcohol-induced ONFH and healthy controls to conduct MassARRAY EpiTYPER test. We report that in the OPG/RANKL/RANK, the methylation levels of some CpG sites in peripheral blood differed between alcohol-induced ONFH cases and controls and that Hypermethylation was observed more often in alcohol-induced ONFH cases than in controls. Therefore, the change of DNA methylation level in OPG/RANKL/RANK may be helpful for the detection of alcohol-induced ONFH.

Abbreviations

ONFH: osteonecrosis of the femoral head

OPG: Cytosine-phosphate-Guanine

DNMT1: DNA methyltransferase 1

ROC: Receiver operator characteristic

AUC: area under curve

BMSC: bone marrow mesenchymal stem cells

RANKL: activator of NF ligand

OPG: osteoprotegerin

RANK: activator of NF- κ B
