Abstract

The accurate diagnosis of tuberculosis (TB), detection of drug-resistant TB and knowledge of the associated risk factors can reduce transmission of TB in the community. Therefore this study was carried out to determine the prevalence of *Mycobacterium tuberculosis* (*MTB*) and its resistance to Rifampicin using GeneXpert in presumptive tuberculosis patients attending some hospitals in Kaduna, Nigeria. A total of 198 sputum samples were collected and screened from participants who had been administered questionnaires using Ziehl Neelsen Acid Fast Bacilli (ZN AFB) method and GeneXpert molecular technique. Data obtained showed that using the Zn AFB staining technique, *MTB* was seen in 65 sputum test results and not seen in 133 sputum test samples but with the GeneXpert technique, *MTB* was further detected in 15 out of these 133 sputum sample thus confirming that GeneXpert was more sensitive in detecting TB compared to the ZN AFB method. The overall prevalence of TB and Rifampicin resistant TB (RRTB) was 40.4% and 1.25% respectively. A higher prevalence rate was reported among male subjects (47.2%), age group 31-40 years (50.9%), those who earned less than 20,000 Naira monthly (41.8%), HIV positive subjects (54.5%), subjects that smoke cigarettes (72.2%) and those that has previous contact with someone living with TB infection (82.4%). Those who had lived with someone having TB disease also had higher RRTB prevalence (100%). Assay for statistical significance showed that independent variables that were significantly associated with the rate of occurrence of TB (p<0.05 at 95% C.I) were Age, Gender, HIV Status, smoking behavior and previous contact with someone having TB. The only RRTB case detected was a male within the age range 31-40 years who does not smoke or take alcohol with Negative HIV status but has had a previous contact with someone living with TB infection. This study indicates a low burden of rifampicin resistant tuberculosis among the participants. It is thus concluded that rapid detection of TB and Rifampicin resistant strains using GeneXpert and other molecular techniques for TB diagnosis in clinical settings is key to early access to the right therapy; it will also improve treatment outcomes and decrease transmission rates.

Introduction

Tuberculosis (TB) is an air borne infectious disease caused by the *Mycobacterium tuberculosis* (*MTB*) (WHO, 2015; WHO, 2020). It is a global health concern as it is the top cause of death from a single infectious agent, rating above Human Immunodeficiency Virus (HIV) / Acquired Immune Deficiency Syndrome (AIDS) (1,2). Tuberculosis usually affects the Pulmonary system (TB of the lungs), where it causes chronic inflammation and progressive lung damage. It can spread to other organs such as joints, liver, kidney and heart (Extra-pulmonary TB) where it causes impaired organ function and eventually death if left untreated. Transmission is mainly through inhalation of air-borne droplets produced when a person with an active infection coughs, sneezes, talks or spits. The risk of getting infected is more common in people with conditions that weaken the immune system (e.g. HIV/AIDS), or those on drugs that suppress the immune system (e.g. cancer patients, organ transplant recipients, patients with auto-immune diseases) etc. In addition, very young age, advanced age, malnutrition, tobacco smoking and alcohol use also increases the risk of TB infection (3).
Rifampicin is by far the most effective anti-tuberculosis agent used in the care and treatment of patients with active tuberculosis (4). It is used in combination with other anti-TB drugs such as isoniazid, ethambutol and pyrazinamide. Rifampicin inhibits synthesis of bacterial proteins that are necessary for cellular activities by inhibiting the DNA-dependent RNA polymerase enzyme (5). In the ensuing years, however, certain strains of *Mycobacterium* have emerged that have evolved resistance to common treatments through genetic alterations (6); thus posing a critical threat to worldwide tuberculosis control. The emergence of rifampicin resistant (RR) and Multi-Drug-resistant (MDR) strains of *Mycobacterium tuberculosis* is a critical challenge to global tuberculosis control (7,8).

In 2019, about 206,030 people were reported to have had MDR-TB globally (WHO, 2020). Of the 10 million incident TB cases worldwide, 500,000 are estimated to have had rifampicin-resistant tuberculosis (RR-TB) (WHO, 2020; Fu *et al*., 2021). Studies in Nigeria reported 12.1–18.8% prevalence of rifampicin-resistant *MTB* (9–12).

In 2010, WHO recommended the use of GeneXpert *MTB*/RIF assay, a fully automated diagnostic molecular test that simultaneously detects TB and rifampicin resistance. It makes use of real-time polymerase chain reaction (RT-PCR) technology to detect specific genes for *Mycobacterium tuberculosis* in a sample (e.g. sputum) and at the same time detect mutations within the 81-base pair region of the beta subunit of bacterial RNA polymerase (rpoB) gene (13).

Early detection of drug resistant strains offers many advantages such as prompt initiation of alternative treatment plan, reduced cost and duration of treatment, and improved patient outcomes (2,7). This research is aimed at determining the prevalence of TB and rifampicin-resistant *Mycobacterium tuberculosis* using molecular methods as well as to identify some risk factors associated with rifampicin resistance among patients presumptive for either TB or drug resistant TB (DR TB) in Kaduna, Kaduna State, Nigeria.

**Materials And Methods**

**Study site, study design and population**

The study design was cross sectional and was conducted within Kaduna metropolis, Kaduna State, Nigeria. Kaduna State is positioned in the North West geopolitical zone of Nigeria. It lies between longitudes 7°45 E and 7.75°E and latitudes 10°20 N and 10.33°N. The state is bordered by Bauchi and Plateau states to the East, Zamfara, Katsina and Kano States to the North, Nasarawa State to the South, Abuja to the South-West and to the West is Niger State. The state has a populace of above 5 million (14) and occupies 46,053 square kilometers. Kaduna city has two main local government area councils: Kaduna South and Kaduna North; nevertheless, a portion of the metropolitan spreads respectively to local government areas of Igabi and Chikun. The research was carried out in the GeneXpert laboratory of the selected facilities under study. There are just 12 GeneXpert sites in Kaduna State. These facilities receive patients from within the state as well as surrounding communities in the adjoining states. The study population was TB-presumptive patients (both males and females from ages
one and above presenting with clinical signs and symptoms indicative of TB) and patients suspected of having drug resistant tuberculosis who presented at the TB clinic unit of the St Gerard’s Catholic Hospital, Kakuri, Kaduna State; General Hospital, Sabo, Sabon-Tasha Kaduna and 44 Nigerian Army Reference Hospital Kaduna, Nigeria during the study period.

**Inclusion criteria and Exclusion criteria**

Samples were obtained from patients known or suspected to have TB, attending clinic at St Gerard’s Catholic Hospital, Kakuri, Kaduna State; General Hospital Sabo, Sabon-Tasha Kaduna and 44 Nigerian Army Reference Hospital Kaduna, Nigeria. All patients included in the study gave a signed written consent before their samples were collected. Patients infected with non-tuberculous mycobacteria (NTMs) and also those that did not consent, were excluded from the study.

**Ethical consideration**

Ethical clearance was obtained from the Ethics and Research Committee of the Kaduna State Ministry of Health and the other selected Hospitals. Permission was also obtained from the heads of TB clinics in all the selected hospitals prior to data and sample collection. Patients’ privacy and confidentiality were preserved as all personal information that could link a patient to the study was removed from the study.

**Data collection**

The sampling technique used was a non-probability one where participants were recruited consecutively for six months until the sample size was attained. This technique was adopted due to the rare nature of the event under study, which therefore necessitated the inclusion of patients presenting primarily at the facility as well as those that came on referral. A well-structured questionnaire was administered to all participating subjects in order to obtain information on demographic data such as age, gender and HIV status.

**2.5 Sample collection**

Sputum samples were collected from all prospective patients into appropriately labelled sterile universal specimen bottles. The sputum samples were inspected for the presence of purulent material and bloodstain. The sputum samples were then taken to the laboratory for laboratory processing and analysis.

**Phenotypic detection of *M. tuberculosis* using Ziehl Nielsen staining method**

The Ziehl Nielsen staining method for acid-fast bacilli was performed as described previously (15). In brief, cooled heat-fixed smears of sputum samples prepared on microscope slides were flooded with filtered Ziehl-Nielsen 1% Carbol fuchsin solution (10g of basic fuchsin powder, 100ml of absolute alcohol, 50g of phenol crystals and 900ml of distilled water) and heated gently until vapour just began to rise. The
heated stain was allowed to remain on the slide for 5 minutes and the slides were individually rinsed in a
gentle flow of distilled water until all free stain was washed away. Excess water was drained off the
slides by tilting the slides. The slides were then flooded with 3% acid alcohol (30ml of concentrated
(hydrochloric acid) HCL and 970ml of 95% ethanol) to decolorize for 3 minutes. The smeared slides were
then rinsed thoroughly with distilled water, and flooded with 0.1% methylene blue counterstain (1g of
methylene blue chloride salt and 1000ml of distilled water) for 60 seconds. The stain was then rinsed off
thoroughly with distilled water; the back of the slides were wiped clean, drained, air-dried and viewed
under oil immersion lens using x1000 magnification alongside positive and negative control slides.
Interpretation of results was done using WHO standards (16). Presence of pinkish red rods indicated
presence of acid-fast bacilli while absence of pinkish red rods indicated absence of acid-fast bacilli.

**Molecular detection of *M. tuberculosis* and Rifampicin resistance using the cartridge-based nucleic acid
amplification test**

A cartridge-based nucleic acid amplification test namely the GeneXpert test was used to detect the
presence of *M. tuberculosis* in sputum samples and identify rifampicin resistance in the clinical isolates
obtained. The GeneXpert test was performed according to the manufacturer’s protocol (Cepheid Inc.,
Sunnyvale, CA, USA). In brief, 1ml of sputum sample was added to 2ml of Xpert MTB/RIF proprietary
NaOH and isopropanol-containing sample reagent and mixed vigorously. The mixture was incubated for
15 min at room temperature and transferred into the GeneXpert MTB/RIF Cartridge. The cartridge was
loaded into a GeneXpert instrument and the software was allowed to run. The test also contains *Bacillus
globigii* that served as an internal processing control. Samples that were negative for *M. tuberculosis* but
positive for *B. globigii* were reported as *M. tuberculosis* negative; samples that were negative for both
*M. tuberculosis* and *B. globigii* were identified as invalid. The test by means of polymerase chain reaction
(PCR), amplifies the beta subunit of bacterial RNA polymerase (rpoB) gene. It is also capable of detecting
rifampicin resistance by the failure of one or more of the rpoB-specific molecular beacons to hybridize
properly to the rpoB amplicon. The test results were automatically generated as presence or absence of
*M. tuberculosis*, presence or absence of rifampicin resistance in *M. tuberculosis*-positive samples.

**Data analysis**

Statistical Package for the Social Sciences 23 (SPSS® package version 23) was used to analyze the data
gotten from this study. To describe the research participants in respect to key variables, descriptive
statistics such as frequency and percentage were employed. The result of the research work was also
presented in tabular forms, charts and figures. Majority of the variables were fitted to logistic regression
analysis for multi-factors analysis, and factors related with *M. tuberculosis* risk and rifampicin-
resistance were assessed by computing the odds ratio (OR) and 95% confidence intervals (95% CI).
Statistical significance level was set as <0.05.
Results

Prevalence of TB infection

A total of 198 sputum samples were collected from consenting participants in Kaduna state and screened to detect the presence or absence of active tuberculosis infection. The result of phenotypic detection of AFB in the sputum samples using Ziehl Neelsen staining method is presented in Table 1. The test detected AFB in 65 samples (32.8%) and level of infection was quantified as scanty (2.5%), 1+ (14.1%), 2+ (11.1%), and 3+ (5.1%) according to WHO standars (16). The test was validated by molecular detection of bacterial gene using the GeneXpert test kit. The comparison between both methods is displayed in Table 2 while the analysis of the sensitivity and specificity of both methods is shown in Table 3. Of the 133 (67.2%) participants that were screened to be free of the infection using AFB method, 15 (7.6%) were confirmed positive using the GeneXpert molecular method. This difference is statistically significant at (p= 0.0001; p<0.05).

The result above depicts the findings of sensitivity and specificity from the screening tests of GeneXpert and Ziehl Nielsen of patients with tuberculosis. The sensitivity of the test reflects the probability that the screening test will be positive among those who have the disease. In contrast, the specificity of the test reflects the probability that the screening test will be negative among those who do not have the disease.

Thus, the sensitivity result from the GeneXpert machine suggested that a patient infected with *Mycobacterium tuberculosis* is 100% likely to test positive with tuberculosis, while the value from specificity analysis revealed that if the patient is not infected with the *Mycobacterium tuberculosis*, there is 100% probability that the test will be negative.

Comparatively, the sensitivity result from the AFB ZN staining technique suggested that a patient infected with *Mycobacterium tuberculosis* is 81.3% likely to test positive with tuberculosis while the specificity result revealed that if the patient is not infected with the *Mycobacterium tuberculosis*, there is 100% likelihood that the screening test will be negative. Therefore, as shown in Figure 1 below, our findings show that the GeneXpert test is more effective than AFB ZN in screening for *MTB*.

### Prevalence and Risk factor of TB in relation to some socio-demographic parameters

As shown in Table 4, the prevalence of TB in relation to socio-demographic parameters revealed that 108 (54.5%) males participated in this study and 51 (47.2%) showed presence of active TB infection while 29 (32.2%) females out of 90 (45.5%) had TB. TB infection was most prevalent (50.9%) among the 31-40 years age group and least (30.3%) among >40 year olds. The investigation also shows that out of the 198 respondents that were interviewed, those that earned less than N20,000 with frequency of 146 (73.7%) had the highest prevalence (41.8%) of *MTB* infection. The difference in the rate of occurrence of TB in relation to these demographic factors showed statistical significance with gender and age at 95% confidence interval. Health factors such as HIV infection, alcohol consumption, smoking and contact with someone with TB were all assessed for association with the prevalence of TB infection. Of the total test results (198), 154 (77.8%) are HIV negative subjects while 44 (22.2%) are HIV positive subjects. Out of these 44 HIV positive subjects, 24 (54.5%) were infected with *MTB*. There was significant association between TB and HIV status at (OR =2.749, 95% CI: 1.192 – 6.340, p=0.018), this implies that a subject infected with HIV is 2.749 times more likely to have TB than a subject without HIV.
The relationship between TB prevalence and alcohol consumption showed no association (p=0.061). Out of the 37 participants that take alcoholic substances, 13 (35.1%) were MTB positive while out of the 161 respondents that do not take alcoholic substances, 67 (41.6%) were MTB positive.

Cigarette smoking was found to be associated with the prevalence of TB in this study (OR =7.077, 95% CI: 1.861–26.923, p=0.004), suggesting that cigarette smoking is risk for TB disease. By implication the likelihood of having TB is 7.077 times higher for subjects who smoke cigarette than in subjects who do not smoke cigarette. Of the 198 participants, 180 (90.9%) do not smoke cigarettes while 18 (9.1%) do smoke cigarettes. Of these 180 participants that do not smoke, 67 (37.2%) were MTB positive while of the 18 that smoke, 13 (72.2%) were MTB positive.

Also, living with someone that has TB infection showed a statistically significant association with the prevalence of TB (OR =12.770, 95% CI: 5.322–30.639, p=0.0001), this connotes that subject who had contact with person with TB disease is 12.770 times more likely to have TB than subject who had no contact with TB patients. From the 198 participants, 51 (25.8%) had lived with someone with TB from which 42 (82.4%) were TB positive, 147 (74.2%) had not lived with someone with TB from which 38 (25.9%) were TB positive.

Factors with ** p-values are 5% statistically significant

Prevalence of rifampicin-resistant *Mycobacterium tuberculosis* in clinical samples
Mutations within the 81-base pair region of the rpoB gene were investigated via GeneXpert methods. The result showed that out of the 80 (40.40%) sputum samples that were positive for \textit{MTB}, only 1 (0.51%) was rifampicin (RIF) resistant (Fig. 2).

**Percentage distribution of some health care related factors that might be associated with TB infection.**

Out of the 49 (24.7%) participants that had previous history of TB, 14 (28.6%) did not adhere to treatment, 2 (4.1%) were not enlightened on the duration of treatment and 3 (6.1%) were not informed by the health care providers on the need for adherence to drug treatment.

**Discussion**

In this study, the prevalence of TB, Rifampicin resistance tuberculosis as well as factors associated with development of TB and rifampicin resistance is shown. The diagnostic yield of Gene Xpert to detect \textit{MTB} in sputum samples have also been evaluated and compared with AFB Ziehl Neelsen method. This study recorded overall prevalence of TB infection and Rifampicin resistance as 40.4% and 1.25% respectively.

The prevalence of TB infection recorded in this study is similar to 35.6%, 31.4% and 37% reported from Akure, Nigeria (10), Lagos and Jos, Nigeria (17) and Pakistan (18) respectively. However, it was lower compared to reports from Zaria (88.6%) (19), and Saye Zaria (40.5%) (11). In contrast, our study showed a higher prevalence than studies conducted in Borno (19.1%) (20), Makurdi (25.5%) (21), Ogun (16.7%), (22), Calabar (24.8%) (23) and Ethiopia (23.2%) (24). These differences might be due to difference in the methods used for detection of \textit{M. tuberculosis}, the nature and type of subjects included in the study, the hospital used (Special \textit{MTB} Referral hospitals, DOTs Centres etc), degree of endemicity of Tuberculosis infection and the geographical area where the study population was located.

Age group of 31 – 40 years had the highest proportion of GeneXpert positive \textit{MTB} cases (50.9%), this data is statistically significant. This finding is in tandem with previous reports in Kano (25) and Ogun State (22). Tuberculosis affects adults generally in their prime working age (3). Exposure to risks factors such as indiscriminate sexual acts by this sexually active reproductive age group, imprisonment, smoking and migration, which is more common among this economically productive age group, might be another reason. This study was however contrary to another report in Nigeria that showed that TB infection was higher in age group 40years and above (26).

The prevalence of \textit{TB} was significantly higher in males (47.2%) than females (32.2%). Reports from Ogun (22), Ethiopia (24) and (2) support this finding. The reason for this could be because males are more involved in interacting with the outer environment due to work activities and travelling and as such are more liable to inhalation of the bacilli from the environment than the female counterparts. Another reason for this gender bias may be the effect of sex hormones and genes linked to the X chromosome, on the immune system (27). Females have higher resistance to microbial infections in humans, implying
that females have a more robust immunological defense against most invading pathogens (28). Estrogen stimulates the immune system, whereas testosterone suppresses it (29). Testosterone has also been proven to inhibit the immune system by upregulating anti-inflammatory cytokines (IL-10), whilst estrogen boosts the immune system by upregulation of pro-inflammatory cytokines. (TNFα) (27). Despite the fact that majority of studies are in line with this finding. In a particular study, it was reported that more females were infected with TB (30).

Human Immunodeficiency Virus (HIV) comorbidity is a confounder factor for the TB diagnosis (31). In our study, the rate of HIV/TB co-infection was 54.5% and this coinfection is found to be statistically significant. Out of the total 198 respondents, the rate of HIV/TB co-infection was 12.1% (24 out of 198); this is in accordance with reports from Nigeria where the TB prevalence among HIV Clients at Global Fund supported facilities by zone and state was studied and TB/HIV coinfection prevalences for Kaduna state were found to be 8.2% from January to June, 2015 (32). Similar rate of 9.5% has also been reported in Edo State (33). It was observed from this study that the risk of developing TB is 2.749 times greater in people living with HIV than among those without HIV infection. According to WHO (2019), the risk of developing TB is 16-27 times greater in people living with HIV than among those without HIV infection. A higher prevalence of 16.6% and 22.2% were reported in studies carried out in Ethiopia (24); and Makurdi, Benue state (21) respectively. A much lower rate of 1.9% was however reported in Saudi Arabia by (34). Variations in this data may be due to the epidermicity of HIV infection in the locations and also the study population. Tuberculosis is a major health risk, particularly for those individuals living with HIV, due to the fact that their immune system is compromised. TB is one of the top causes of mortality among HIV-positive persons globally.

Furthermore, this study also confirmed that using Genexpert for the detection of TB was more sensitive and had more diagnostic yield than AFB Ziehl Neelsen smear microscopy method. Our findings showed that 133 (67.2%) samples tested were AFB smear negative, but Genexpert was able to detect the presence of \textit{MTB} in 15 (7.6%) smear negative sputum samples scaling down those with true negative results to 118 (59.6%). Majority of the cases that went undetected by smear microscopy were from patients with TB/HIV coinfection. This result is congruent with the findings of a comparative study of Genexpert with Ziehl Neelsen stain in samples of probable pulmonary TB patients (35) where the sensitivity of Genexpert in sputum assay was found to be 100%. This is because even low \textit{MTB} genomic copies in various specimens can be detected and as such, has the ability to profoundly improve tuberculosis case detection in areas such as AFB Ziehl Neelsen staining method where conventional diagnostics have been woefully inadequate especially in people with suspected HIV-associated TB with very low \textit{MTB} genomic copies (36).

People with immune systems that are compromised, such as smokers, have an increased risk of contracting TB infection and falling ill (3). It was discovered from this study that 6.6% out of the 9.1% participants that smoke cigarette were infected with \textit{MTB} thus significantly relating smoking to be a
factor that increases the risk of contracting TB. This is in agreement with researches carried out in Nigeria (23,37), Korea (38), and South Africa (39) where it was discovered that smoking was linked to an increased risk of both incidence and recurrence of TB infection. This relationship is likely because smoking has a wide range of consequences on pulmonary structure and function and has an effect on host defenses both in the lung and throughout the body system thereby affecting the immune system and making people more susceptible to TB disease (40). It was observed from the study that the participants who smoked is 7.077 times more likely to be TB infected than participants who do not smoke.

The relationship between TB infection and income earned was also shown in this study. Participants who earned less than 20,000Naira in a month had the highest prevalence (41.8%) of TB infection. This just further buttresses the fact that TB infection is more common among people with low income (41).

This study further revealed the relationship between developing TB infection and previous contact with someone infected with TB. This was found to be statistically significant and therefore corroborates the findings that people with active TB can infect 5–15 other people through close contact over the course of a year (3). This is also in agreement with previous reports from Croatia (42) and Ibadan, Nigeria (43). These reports indicated that contact with TB patients was a significant behavioural factor for TB transmission.

From this present study, it was discovered that the difference in the rate of occurrence of TB in relation to whether the respondents consumed alcoholic drinks or not, is however not statistically significant Out of the 37 respondents that consumed alcoholic substances, 13 (35.1%) were MTB positive. This contradicts a research that found alcohol intake to be a major risk factor for TB, most especially heavy use of more than 40g of ethanol per day, which resulted in a roughly three-fold increase in TB risk (44). The reason for this variation may be because participants who consumed alcohol in this study were not heavy consumers.

This study recorded overall prevalence of Rifampicin resistant TB in the three hospitals studied in Kaduna State at 1(1.25%). This findings is similar to the work that reported 2% in Lagos state (45) and 4.2% from a study on the prevalence of Rifampicin resistant TB among patients that have been previously treated for pulmonary TB in Nigeria’s North western region (46). This data is also congruent with the Global TB reports by WHO in 2016, which show low levels of MDR/RRTB (< 3%) in new TB patients in various regions globally (41). The overall findings is however lower than 6.1% cases in Borno State Nigeria (20) and 7.3% in Delta State (47). Much higher prevalences of 49.1%, 18.8%, 13.6%, 14.7% and 29.4% were however found in other studies in India, Yenagoa, Saye Zaria, Akure and Makurdi and respectively (10,11,21,48,49). The difference in the various prevalence rate could be traced to the extent and burden of MDRTB/RRTB in the geographical location, test methods used, sample size, poor record and data keeping. Anti-TB drugs exposure, treatment practices and implementation of national control programmes could be issues also (50).
Furthermore the RRTB case detected has had a previous contact with someone living with TB infection. This implies that the participant directly contracted the Rifampicin resistant strain. Transmitted or primary drug resistant TB results from the direct transmission of drug resistant *MTB* strain from one person to another (1). The emergence and prevention of primary drug resistant tuberculosis has been generally overlooked in the creation of worldwide anti-TB campaigns to stop TB. It was previously thought that the majority of drug-resistant tuberculosis was caused by acquired tuberculosis. Researchers have been able to explore this deeper due to the use of modern techniques, and they have discovered that primary resistance has a far greater role in resistance than previously assumed (1).

**Conclusions**

Data from this study has shown that Rifampicin-resistant strains of *MTB* is not as prevalent in the study area as compared to other areas in this part of the country.

The prevalence of Rifampicin resistant TB reported in the study may be lower compared to other reports but it still stands that even the lowest prevalence rates of MDR-PTB remains a major public health issue. Findings from this study should provide critical patient management decisions regarding treatment and successful patient outcomes, help planning of effective public health control measures and provide information for data based decision making and adequate planning for infection control and treatment by the facility management and National TB Control. This study should also serve as a guide for similar future researches. The use of GeneXpert should be increased all over the country for rapid management, diagnosis and enhanced monitoring of TB and drug-resistant TB.

Further in-depth studies should also be carried out on drug resistance to other first line and second line drugs. The genes responsible for these resistances should also be identified and studied. The variables highlighted in this study should serve as potential targets for further studies using a larger sample size.

**CONFLICT OF INTERESTS**

The authors have not declared any conflict of interest.

**ACKNOWLEDGEMENTS**

The authors acknowledgement goes to the Staff of the Department of Medical Laboratory Science, St Gerard’s Catholic Hospital, Kaduna especially the HOD, H. Nwobodo; B. Adu and Madam Celine for their support during the course of this work. We wish also to appreciate A. Owo, and Mr Abraham from 44 Nigerian Army Reference Hospital Kaduna for their support. Special thanks also goes to Miss Mary of the DOT department, General Hospital Sabo, Kaduna; The ethical committees of the selected hospitals and all those who particularly volunteered as subjects and helpers for this work.
