Abstract

Background

The key differences in cell death mechanisms in the trabecular meshwork (TM) in adult moderate and severe primary glaucoma remain still unanswered. This study explored key differences in cell death mechanisms in the trabecular meshwork (TM) in adult moderate and severe primary glaucoma.

Methods

Select cell death related proteins differentially expressed on mass spectrometric analysis in ex-vivo dissected TM specimens patients with severe adult primary open angle (POAG) or angle closure glaucoma (PACG) compared to controls (cadaver donor cornea), were validated for temporal changes in cell death related gene expression on in-vitro primary human TM cell culture after 48 hours (moderate) or 72 hours (severe) oxidative stress with H2O2 (400-1000uM concentration). These were compared with histone modifications after oxidative stress in HTM culture and peripheral blood of patients with moderate and severe glaucoma.

Results

Autophagy related proteins seemed to be the predominant cell death mechanism over apoptosis in ex-vivo dissected TM specimens in severe glaucoma. Analyzing HTM cell gene expression at 48 hrs and 72 hours of oxidative stress, autophagy genes were up-regulated at 48 hours of exposure > 72 hours which was in contrast to apoptosis related genes showing down-regulation at 72 hours. There was corresponding preferential abrupt upregulation of autophagy genes in the peripheral blood of the patients with severe glaucoma with associated increased expression of H3K14ac in HTM after 72 hrs of oxidative stress and in peripheral blood of severe POAG and PACG patients. Necrosis seemed to play a minimal role in cell death in moderate or severe stress in cell lines or peripheral blood.

Conclusion

A preference of autophagy over apoptosis may be underlie the mechanism of stage transition from moderate to severe glaucoma in the trabecular meshwork or peripheral blood which may be tightly regulated by epigenetic modulators. Associated epigenetic control mediating the unidirectional upregulation of autophagy in severe glaucoma requires to be explored.

Background:

Primary open angle (POAG) and primary angle closure glaucoma (PACG) are the two most important forms of adult primary glaucoma seen worldwide. The primary site of injury is the trabecular meshwork,
TM, which contains collagen beams and endothelial cells with extracellular matrix (ECM) interspersed between the cells and represents the site of maximum resistance to aqueous outflow. Thus, this tissue plays an important role in the pathogenesis of glaucoma and understanding the mechanism of its dysfunction is key for preventing or reversing functional TM damage. In glaucoma, the TM cells are presumed to die by apoptosis though several other mechanisms of cell death are possible. The human TM cell lines, and ex-vivo dissected TM tissue obtained from normal donors has been reported to express several modulators of apoptosis along with abundance of heat shock proteins (HSPs). Apoptotic modulators have been expressed in ex-vivo T specimens or TM cell in culture and have also been shown to be up-regulated upon stress on in-vitro TM cell lines. Oxidative stress markers have also been found to be very highly expressed in aqueous humour and anterior segment tissue in glaucoma eyes. Several studies have reported increased expression of pro-apoptotic molecules in the anterior segment or ocular tissues including TM in glaucoma, human TM cell lines, and ex vivo dissected TM tissue obtained from normal donors, express several modulators of apoptosis (Fas, Bcl-2, Bcl-Xl, Bax, and caspases). Literature on autophagic process in glaucoma is limited and focus on expression of autophagy genes in tissue of the anterior segment or in-vitro experiments. Further, autophagy participates in myocilin degradation which is known to be involved in POAG pathogenesis in humans. Studies have shown that autophagy process is inducted early by bi-axial stretch and in perfused eyes subjected to raised IOP.

Glucoma being a progressive disorder, would logically cause gradual damage and cell death involving alteration in multiple cell death signaling events including impaired cross talk between apoptosis and other cell death mechanism like autophagy. Our earlier study on HTM cell lines showed definite morphological differences apart from differential MMP expressions with varying time period of exposure to oxidative stress reflecting that cell death mechanisms may be different with different severity of the insult. Yet, the exact molecular mechanisms in-vivo regulating cell death/functioning in the TM tissue at different stages of glaucoma is not yet elucidated. This study explores the differential role of cell death process in the TM in different stages of glaucoma.

**Methods:**

**Clinical characterisation of glaucoma cases and controls and sample collection**

The inclusion criteria included POAG or PACG (defined as pre-treatment IOP ≥ 21 mmHg, open or closed angles on gonioscopy with glaucomatous disc features like rim loss or notch, vertical cup disc ratio > 0.6 asymmetry of more than 0.2, retinal nerve fibre layer loss or disc hemorrhage) with at least three reliable baseline preoperative visual fields, no retinal or neurologic disease that may have affected the visual field. Only patients with established glaucoma scheduled for surgery for glaucoma for uncontrolled IOP were included for the study which adhered to the tenets of declaration of Helsinki and was approved by
the institutional review board. All patients included for the study underwent detailed examination after a written informed consent. Patients were diagnosed as POAG in the presence of open angle on gonioscopy, IOP > 22 mm Hg and visual field/disc changes consistent with glaucoma. PACG was diagnosed in the presence of closed or occludable angles on gonioscopy with IOP > 22 mm Hg and glaucomatous visual field/disc changes.

Glaucomatous visual field defects were diagnosed according to Hodapp-Parisch criteria and only reliable fields were taken for final analysis. We classified these patients into moderate and severe glaucoma based on visual field indices namely the mean deviation or MD. Patients with MD <-12dB were classified as severe and those with MD>12dB and <-6dB were classified as moderate glaucoma. Only those that fulfilled the above criteria in both eyes were selected with the worse eye taken for analysis.

The TM specimens were obtained according to standard surgical procedures of limbus or fornix based trabeculectomy with a vannas scissor. They were obtained from patients undergoing surgery for uncontrolled IOP (only glaucoma surgery) and/or associated cataract. For all analysis, the TM was snap-frozen in liquid nitrogen and stored at −80 °C until further assays. Since usually severe glaucoma patients undergo surgery with medical treatment being preferred in moderate cases, proteomic analysis was done for surgical samples procured only from those with severe glaucoma.

Control tissues were obtained from donor eyes harvested from the eye bank or from cadaver eyes with no history of glaucoma in patient and family. A 5 × 5 mm corneo-scleral block was dissected from these donor eyes in the same manner as above. The trabecular meshwork may contain scleral contamination but a majority of tissue would have trabecular meshwork tissue.

**Proteomic analysis of Ex-vivo surgically dissected TM specimens**

To test for cell death markers, we analyzed ex-vivo dissected TM specimens obtained from patients with severe POAG or PACG (n = 3 each), uncontrolled IOP and stable visual fields undergoing surgery and 25 controls (donor corneal buttons without any ocular pathology obtained from the institutional eye bank) for protein expression profile in the trabecular meshwork with regards to specific cell death pathways which may be more predominant in severe glaucoma stages.

Excised tissues were dissolved in 150 ul of chilled 6M Gn-HCL in 0.1M Tris (pH 8.5) plus 1× protease inhibitors (Roche). Tissues were dissolved using tissue homogenizer and then sonicated at 60 amplitude, 10sec on and off for 5 minutes for mass spectrometric analysis. Homogenized samples were boiled at 90°C for 5 minutes and then centrifuged at 15000 rpm for 20 minutes at room temperature. The supernatant was stored and marked properly. Protein concentration of all the lysates were performed using BCA method (Thermo) and 25 µg of the protein lysates were first reduced with 5 mM TCEPTris (2-carboxyethyl) phosphine hydrochloride followed by alkylation with 50 mM iodoacetamide. For tryptic digestion, the samples were diluted to 0.6M final Gn-HCL concentration using 25 mM ammonium bicarbonate buffer and trypsin protease (promega gold) added into the reaction (1:50, trypsin:lysate ratio).
for 16 hours at 37 °C. The peptide digests were purified using C18 silica cartridge (The Nest Group, Southborough, MA) as per manufacturer’s protocol and finally dried using speed vac at 50 degree temperature. The dried purified peptide pellet was stored at -20 degree and before nano-ESI LC MS/MS run, re-suspended in Buffer-A (5% acetonitrile / 0.1% formic acid).

For Label Free Quantification analysis the peptide samples were resolved using EASY-nLC 1000 system (Thermo Fisher Scientific) which was connected to QExactive orbitrap mass spectrometer (Thermo Fisher Scientific) equipped with nanoelectrospray ion source. 1 µg of the peptide mixture of each sample was loaded on a C18 precolumn and resolved using 50 cm Easy-spray LC column (Thermo Fisher Scientific). The peptides were loaded with Buffer A and eluted with a 0–40% gradient of Buffer-B (95% acetonitrile/0.1% formic acid) using a run time of 90 minutes at a flow rate of 300 nl/min. The run program of QExactive was performed with Top10 HCD data-dependent positive polarity acquisition mode with a full scan and MS/MS scan resolution of 70,000 and 17500 at m/z 400 respectively. For internal recalibration during the 90 minute run, lock mass option was enabled for polydimethylcyclosiloxane (PCM) ions (m/z = 445.120025).

The RAW files generated from all the LC MS/MS runs were analyzed with Proteome Discoverer (v2.2) against the HUMAN swissproteome database (20366 entries). For Sequestsearch engine the mass tolerances for MS and MS2 were set at 10 ppm and 0.5 Da, respectively. Fully tryptic enzyme setting with maximum two missed cleavage and fixed modification (Cysteine, Carbamidomethyl) and variable modification (methionine, oxidation) were used in extra settings. For 1% FDR (False discovery rate) percolator node was used for both peptide spectrum matches and protein FDR. Label Free Quantification was performed using the Precursor Ion Quantifier node (Minora Feature Detector) included a Minimum Trace Length of 5, Max. ΔRT of Isotope Pattern 0.2 minutes.

The softwares used for data analysis included the Thermo Proteome Discoverer (v2.2), Perseus (v1.6.0) and STRING (Online software). Since temporal changes of cell death pathways cannot be demonstrated in ex-vivo dissected specimens which also have less/very variable number of viable cells with extensive fibrous tissue at the time of surgery, select candidate proteins of the discovery stage belonging to autophagy and apoptosis were now taken up for validation studies on human trabecular meshwork primary cell cultures for temporal changes in expression of cell death markers. Detailed methods for data analysis are given separately, Supplemental Methods and appendix.

**Cell death mechanisms in-vitro on HTM cell culture after H2O2 induced stress**

Validation of cell death markers was done in commercially available primary human trabecular meshwork (three different strains HTM, Cell applications, Inc, CA) obtained as gift from CSIR, New Delhi and validated with dexamethasone induced myocilin expression) cells. These cells (not immortalized lines) were cultured with Dulbecco’s Modified Eagle Medium, DMEM, medium containing low glucose, sodium pyruvate and sodium carbonate. Media was supplemented with 10% fetal bovine serum (FBS),
4 mM of L-glutamine and 1% of antibiotics penicillin/ streptomycin, antimycotic solution. For experiments 3rd -5th passage cells were taken for analysis.

**Cell death related gene expression after H2O2 induced stress on HTM culture**

For cell viability assay human trabecular meshwork (HTM) cells were grown in a 96-well plate (Tarsons) for 24 hours in 100 µl of DMEM media with a seeding density of 6000 cells/well. The cells were treated with 100 µM, 200 µM, 400 µM, 600 µM, 800 µM and 1000 µM of H$_2$O$_2$ for 12hrs, 24 hrs, 48 hrs and 72 hrs under serum-starved conditions. Viability of cells was analysed by a MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay. The media was removed, and 100 µl MTT solution (0.5 mg/ml) was added to each well for 3 hrs at 37 °C. The formazan crystals that formed were dissolved by the addition of 4 mM dissolving solution after removal of supernatant. Absorption was measured with a spectrophotometer at 570 nm.

A total of 1 million HTM cells were cultured in a T-25 flask with DMEM medium supplemented with 10% fetal bovine serum (FBS). The cells were treated with 600–1000 µM of H$_2$O$_2$ for 12, 24 and 48 and 72 hrs. After treatment the cells were harvested and washed twice with 1 ml of 1X binding buffer followed by centrifugation at 300xg for 10minutes. The supernatant was aspirated and the pellet was re-suspended in 100 µl of 1X binding buffer. 10 µl of Annexin V-FITC was added and incubated for 15 minutes in dark at room temperature. The cells were washed twice with 1 ml of 1X binding buffer followed by centrifugation at 300xg for 10minutes. The supernatant was aspirated and the pellet was re-suspended in 100 of 1X binding buffer followed by addition of 5 µl PI (propidium iodide 10 mg/mL) before flow cytometry analysis.

Total RNA was extracted from HTM cells using QIAzol® Lysis reagent (QIAGEN). The homogenized mixture of QIAzol and cells were kept at room temperature for 5 minutes to permit complete dissociation of nucleoprotein complexes followed by chloroform mixed vigorously for 15 second at room temperature for 2–3 minutes. The resulting mixture was centrifuged at 12000 x g for 15 minutes at 4 °C and the aqueous phase was transferred into a fresh tube for precipitation with 0.5 ml of isopropanol and 5 µl of RNase free glycogen (5 µg). This was followed by centrifugation at 12000 x g for 15 minutes at 4 °C after which the RNA pellet was washed with 75% ethanol and final centrifugation at 7500 x g for 5 min at 4 °C before finally dissolved in 20 µl DEPC water. The purity and amount of RNA were determined by measurement of the OD260/280 ratio. Pure RNA was ensured aftereliminating with genomic DNA which was then reverse transcribed using the First Strand Synthesis Kit (Qiagen) and subsequently loaded on to apoptosis, autophagy and necrosis RT$^2$ profiler array according to manufacturer’s instructions (comparative and fold change was calculated by determining the ratio of mRNA levels to control values using the ΔCt method (2$^{-ΔΔCt}$). The online Qiagen analysis tool was used for computing comparative fold changes calculated by determining the ratio of mRNA levels to control values using the ΔCt method (2$^{-ΔΔCt}$). All data were normalized to an average of five housekeeping genes ACTB, GAPDH, HPRT1, RPLP20 and HGDC. PCR conditions used for analysis was 10 min at 95 °C, followed by 40 cycles of 15 s
at 95 °C and 60 s at 60 °C. The p values were calculated based on student's t-test of the replicate $2^{(-\Delta\Delta CT)}$ values for each gene in the control group and treatment groups and $p < 0.05$ was considered significant.

**Epigenetic control of cell death mechanisms**

Since switch of cell death pathways is governed by tight epigenetic control in tissue and peripheral blood, we evaluated expression of specific epigenetic regulators. Histone modifications were studied using the EpiQuik Histone H3 Modification Multiplex Assay Kit (Colorimetric) according to manufacturers protocol and selected modifications significantly upregulated in cell lines after stress induction were validated using immunoblotting.

Total proteins were extracted from HTM cells using 1X lamelli buffer (2% SDS, 10% glycerol, 50 mM Tris (6.8), bromophenol blue (0.05%), β-mercaptoethanol). Protein samples were strongly vortexed and boiled at 95 °C for 5 minutes and then sonicated at 40% amplitude 10 sec on and off for 1 minutes. Extracted samples were centrifuged at 12000 rpm for 2 minutes. Protein samples were resolved in 10% SDS-PAGE (Bio-Rad Laboratories) and transferred to nitrocellulose membrane (Immobilon-N; Merck Millipore) using a mini trans-blot electrophoretic transfer system (Bio-Rad Laboratories) and probed with the following primary antibodies: anti-H3 (1:10000), anti-H3K14ac (1:5000), anti-H3AK5ac (1:3000), anti-H3K18ac (1:3000) was used and bands were visualized by using enhanced Chemiluminescence (ECL) from Bio-Rad Laboratories. The blots were analyzed using gel-Doc system (Bio-Rad laboratories) analysis. All experiments were carried out in triplicates.

**Change in gene expression in peripheral blood**

Since the TM tissue is bathed with aqueous humor, comparing changes in the peripheral blood versus the tissue changes would give an insight if the local tissue changes may represent an effect of peripheral stimuli or a local response restricted to the TM tissue only. We therefore compared the gene expression in the peripheral blood of these patients whose ex-vivo dissected TM specimens were analyzed. Whole blood was collected from patients whose TM specimens were collected (POAG, PACG and control (cataract)) into EDTA tubes. In addition, those with moderate stable glaucoma (not undergoing surgery) were also analyzed for gene expression in peripheral blood to compare with those with severe glaucoma. Whole blood was diluted with 1X phosphate-buffered saline (pH 7.2) in the ratio of 1:1. Aseptically 2.5 ml of Hisep LSM (Himedia) was overlaid with 7.5 ml of diluted blood in the proportion of 1:3 followed by centrifugation at 400Xg at room temperature for 30 minutes to separate the lymphocyte layer which was carefully aspirated. Equal volume of 1X PBS was added and mixed by gently aspiration and centrifuged at room temperature at 300xg for 10 minutes. Cell death analysis by FACS and gene expression for cell death related genes (described above) was carried out in PBMC. Immnuoblotting was used to study histone modifications in PBMC as detailed earlier.

**Results:**

Autophagy and apoptosis proteins in ex-vivo dissected TM tissue in severe glaucoma
while autophagy predominant over apoptosis in HTM cells after severe oxidative stress

Table 1 gives the demographic and clinical characteristics of patients included in the study. Of 1813 proteins identified, we found a total of 797 unique elements in POAG and PACG compared to controls with a total of 12 identifiable and quantifiable proteins in POAG and 7 in PACG proteins were found to be differentially expressed compared to controls, Figure 1. We also found myocilin and AQP1 apart from other proteins which were specific markers for TM tissue, Table 2. Categorising proteins according to functional relevance, we could see overall distribution of the 797 proteins in diverse cellular functional categories with most proteins in POAG and PACG were involved in response to stimulus and defence response, cell death and cell movement organisation. Most of them were extracellular or membrane proteins (as opposed to membrane proteins in controls) involved in protein binding and catalytic activity or structural molecule activity, Fig. S1.

Both POAG and PACG TM tissues had several proteins which were significantly different from that of controls of which most were either ECM related or cell death proteins, Fig S1 and S2. Both apoptosis and autophagy proteins were overexpressed in severe POAG > PACG samples compared to controls. Notably, apoptotic protein, caspase14, was under-expressed in severe POAG and PACG specimens while autophagy related LAMC1 protein was overexpressed in severe POAG > severe PACG, Fig S1. We also found endoplasmic reticulum stress markers namely, translation initiation factor2α (eIF2) and ER chaperone GRP78 (glucose-regulated protein) to be overexpressed in POAG and PACG compared to controls, Table 2.

Stress induction on in-vitro HTM cell lines with reduced cell survival was seen to start at 400-1000uM concentration at 48-72 hours and this response correlated with maximum cell death at 72 hours, Fig 2. Flow cytometry results also showed parallel changes with maximum apoptotic cells at 48 hours with some necrotic cells also seen at 24-48 hours.

Analyzing HTM cell gene expression at 48 hrs (similar to moderate glaucoma) and 72 hours (maximum cell death similar to severe glaucoma stage) of oxidative stress, autophagy genes were parallelly up-regulated at 48 hours of exposure>72 hours which was in contrast to apoptosis related genes showing down-regulation at 72 hours, Fig 3. Apoptosis genes were up-regulated at 48 hours of H2O2 exposure while several genes like BCL, FASL and CASP7 were down-regulated after 72 hours of exposure simulating changes in HTM tissue specimens in severe glaucoma. Necrosis genes were also seen to maximally up regulated at 48 hours compared to 72 hours where most genes were down regulated or minimally functional, Fig 3.

Switch to Autophagy in peripheral blood of severe glaucoma and epigenetic control of cell death

Flow cytometry on PBMC showed significantly higher (>2 times higher) pro-apoptotic and apoptotic PBMC cells in glaucoma cases and POAG > PACG eyes, Fig S3. Interestingly, autophagy genes showed an abrupt up-regulation of genes like AKT1 and ATG16 seen in severe glaucoma as opposed to down-regulation in moderate POAG and PACG, Fig S4. In contrast, the PBMC cells in severe glaucoma showed apoptotic
genes to be down regulated in severe glaucoma in both POAG and PACG, Fig S4 (E-G) with necrosis genes showing minimal changes between glaucoma stages, Figure S4 (H, I).

These findings suggests that in PBMC, autophagy may be the predominant mechanisms of cell death in severe glaucoma wherein autophagy related process may be the driving force chosen for cell death over apoptosis. This mirrored proteome results in TM dissected tissues and HTM experiments where autophagy related proteins were over-expressed in severe glaucoma. To evaluate if epigenetic regulatory mechanisms may explain this switch in preference of cell death process with different glaucoma stages, we evaluated the histone modifications in PBMC and also on in-vitro cell cultures after stress.

Concurring with several histone proteins over-expressed in TM tissues (Supplemental data), immunoblotting showed increased expression of H3K14ac in severe POAG and PACG, Fig S4 (J,K) while other methylation changes were seen over-expressed only in severe POAG and minimal in other stages of POAG or PACG. Similar results were seen in HTM cell cultures with H3K14ac seen at 72 hours of stress exposure akin to severe glaucoma in PBMC, Fig 3 (D,E).

Discussion:

This study found several proteins and genes related to autophagy to be predominantly expressed over apoptosis in TM tissue or HTM cell lines in-vitro after severe oxidative stress similar to clinically severe glaucoma. In-vitro study showed that autophagy was preferentially favored over apoptosis as cell death/repair mechanism beyond 48 hours (or severe glaucoma phenotype). Similar results were seen in PBMC where autophagy genes were abruptly up-regulated in severe POAG and PACG compared to moderate glaucoma. This was also associated with complete lack of any necrosis related proteins in severe TM tissues and down-regulation of necrosis genes in HTM cells after 72 hours of stress. Tight regulation of the cross talk between autophagy and apoptosis in the TM seems to favor autophagy as predominant cell death/repair mechanism in severe glaucoma.

Autophagy related proteins were identified overexpressed in POAG and PACG TM tissues in this study along with ER markers suggesting a clear role of autophagy in cell death in severe stages of glaucoma. Since a temporal preference of one mechanism over another in patients or on surgical specimens is not feasible, we confirmed that autophagy seems to be preferred over other cell death mechanisms in severe stages compared to moderate stages in PBMC and on in-vitro HTM cell lines after oxidative stress. The exact mechanism by which the cell population is reduced and cell function is altered in different disease stages in glaucomatous human TM tissues is not known, although several potential mechanisms have been suggested, including vacuole mediated phagocytosis and apoptotic death.\(^3\)\(^{-7}\) What mediates the cell death or repair in TM tissue and specific events by which the repair mechanisms get overwhelmed by cell death process in different disease stages is unexplored. Oxidative stress mediated cell death is well known in TM which has been reported in earlier studies confirming the presence of stress markers in aqueous and TM specimens or donor corneas.\(^{10\text{-}14}\) Several apoptosis related molecules have been known to be involved in TM specimens obtained from donor corneas and also in in-vitro HTM cell culture
models after stress. Human trabecular meshwork cell lines can be induced towards programmed cell death via the Fas-FasL pathway suggesting the role of apoptosis in TM cell death. Raised IOP is supposed to create mechanical stress on the TM cells which is tightly regulated via cochlins and other genes to regulate the tone or response to stretch in TM cells. How this destructive cycle is self-perpetuating in moderate or severe stages and what pathways are involved in the TM mediating continued cell death in adjacent normal areas has evaded a clear explanation.

Induction of autophagy has also been shown upon stress on iv-vitro HTM cell lines after oxidative stress or to dexamethasone exposure. It is therefore possible that mechanisms related to those observed in oxidatively stressed TM cells lead to defective autophagic repair in glaucoma disease. One study showed increased autophagy events during TM aging as evidenced by the increase in the LC3 II/I ratio. Cathepsins are known to be directly involved in the autophagosome function and their association with aging indicates that dysregulated autophagy may drive the cell process towards cell death in glaucoma. While several such isolated studies suggest the role of apoptosis and autophagy in the trabecular meshwork in glaucoma, relative contribution of each in different stages of glaucoma regulating cell death is unknown. Our study points towards relative favoring of autophagy over apoptosis or necrosis in severe stages of glaucoma both in tissues and in-vitro cell culture, which is in contrast to conventional thought of cell death being mediated by apoptosis in advanced disease stages. Such biphasic changes in autophagy may presumably be considered to contribute to disease progression in TM tissues in glaucoma.

Disturbances in autophagy are associated with various diseases, including neurodegenerative disorders, such as Alzheimer’s, Parkinson’s and Huntington’s diseases. Porter et al. concluded that the stress induced decrease autophagic activity or repair mechanism in the TM may be responsible for glaucoma pathogenesis. Previous studies have shown that both autophagy and apoptosis regulate key cell functions while coexisting in the same cell through active regulatory feedback loops between the two processes. Autophagy may be initially activated by stress to exert cytoprotective effects until a specific threshold of stress where apoptosis is activated. Reports suggest a dual role of autophagy which can either inhibit or stimulate apoptosis. It is therefore clear that the activation of autophagy may promote cell survival via the inhibition of apoptosis; and the over-activation of autophagy can either promote apoptosis or drive cells to undergo autophagic cell death. Our results suggest that switch to autophagy pathways preferentially over apoptosis in peripheral blood may be the first precursor of changes at the trabecular meshwork or disease progression to advanced stages in glaucoma. This needs further validation on cell based in-vitro or experimental glaucoma model system based modification of these pathways or molecules. It may be argued that apoptosis seen in TM specimens may be the result of several anti-glaucoma drugs which is known to be caused by preservatives. Yet, addition of glaucoma drugs has not shown to induced apoptotic cascades in cell lines suggesting that studies reporting apoptosis in drug treated eyes may actually be a result of the disease per se rather than drug related changes. Besides, we took only patients with severe uncontrolled glaucoma for surgery which entailed that all these eyes were on the same class of maximal medical treatment albeit for
different duration of time before surgery. So the effect of drugs on expression of apoptotic proteins may be considered to be minimal owing to the selection of patients/eyes on all classes of drugs at the time of surgical tissue harvesting.

In TM tissue with severe glaucoma, we found several proteins belonging to apoptosis extrinsic pathway to be under-expressed in both POAG and PACG tissues. In cell lines, while FASL, FAS-R among other molecules seemed to be down-regulated at 72 hours of oxidative stress exposure in contrast to Apaf1 which remained up-regulated. Molecules like Caspases, the effector molecules, mediating the execution phase seem to get down-regulated in severe stress at 72 hours after initial up-regulation at 48 hours (and 24 hours-data not shown). These findings suggest that continued exposure to stress in severe glaucoma seem to overwhelm the apoptotic extrinsic pathway in the TM tissue. This correlates with maximum cell death seen after 72 hours of stress exposure suggesting that cell death in these severe stress conditions occurs by alternate mechanisms like autophagy. Regulation of cell death is one of the prime functions involving various mechanisms tightly regulated and also which have active cross talk between each other which determine the final fate of the cell. Autophagy is activated in response to several stressors like starvation, ER stress and oxidative stress and plays an important role in devilment and disease. While several links between apoptosis and autophagy have been found, exact regulation of this cross talk in different disease is not yet explored. In glaucoma, autophagy seems to be preferred over apoptosis in advanced stages. Whether this is a protective or destructive function in-vivo in peripheral blood or in the TM tissue remains unclear.

We also could not find other ATG proteins or necrosis related proteins in the TM tissue though we found end products of the cell death pathways including casapse 14 which were under-expressed in TM tissues and ER stress markers like GRP78 to be over-expressed in POAG and PACG. In HTM cell cultures, autophagy genes were significantly up-regulated after continued exposure to oxidative stress. We are not sure if these proteins are altered during surgical dissection or are not in quantifiable amounts in the TM tissue. Also it is plausible to expect that earlier proteins like BCN and ATG proteins may not be found in ex-vivo dissected tissues from patients with advanced stage at the time of surgery where the end products of such cascade of events or molecules involved in these end stage process like lysosomal fusion may be seen. So the tissue changes reflect the snapshot of activities that could have taken place earlier.

Histone modifications such as trimethylation of H3 lysine 4 (H3K4me3) and hyperacetylation of histone H3 and H4 are known to cause gene activation and active transcription while methylation of H3K9 and H3K27 are known to be cause gene repression or silencing. Recent evidence shows that HDAC 2 and 3 transcripts are significantly increased with decreased histone H4 acetylation in retinal ganglion cells after acute optic nerve injury. Furthermore, significant differences in genomic DNA methylation have been found in peripheral mononuclear cells from patients with open angle glaucoma compared with healthy controls. Reports also suggest that abnormal histone acetylation/deacetylation may be related to retinal ganglion cell damage in glaucoma. We only found H3Kme3 to be overexpressed in severe glaucoma cases suggesting a possible regulatory role in causing the autophagy switch and cascade in
advanced disease stages. Changes in the peripheral blood may be expected to regulate tissue gene expression which is of interest with respect to the TM. Traditionally, H3 and H4 are known in glaucoma though the role of H2 and H1 was hitherto unknown in glaucoma pathogenesis. It may be possible that such epigenetic changes may underlie the basis of progression which may be IOP dependent or independent. To the best of our knowledge, there is no report to show the role of histone acetylation and other PTMs in the progression of glaucoma or stage transition which requires further research.

**Conclusion:**

In summary, this study shows autophagy proteins and genes predominating over apoptosis or necrosis in severe glaucoma while in moderate cases, each mechanisms of autophagy and apoptosis may be acting independently. The switch to autophagy in peripheral blood or TM tissue seems to be a tightly regulated mechanism of cell death control in different glaucoma stages reflecting that this could be used a surrogate for progression of disease severity in adult primary glaucoma.

BP- design of the work; the acquisition, analysis, the creation of new software used in the work, interpretation of data; ; substantively revised it

SS- design of the work; the acquisition, analysis, interpretation of data; ; substantively revised it

GDJ- design of the work; the acquisition, analysis, interpretation of data; ; substantively revised it

PM- the acquisition, interpretation of data; substantively revised it

RM- design of the work; the acquisition, analysis, interpretation of data; ; substantively revised it

MS- design of the work; the acquisition, analysis, interpretation of data; substantively revised it

all authors have read and approved the manuscript

Acknowledgements-All patients who participated in the study, DrRavindran and BirenderPrusty for helping with cytokine analysis at ILS, Bhubaneswar. We thank MrBikashSahoo for helping us with the FACS analysis on PBMC and HTM cells in KSBT, KIIT.

See appendix for description of proteins; *- Data of log2 fold change values of all proteins have been deposited to the ProteomeXchange Consortium.

**Figures**
Figure 1

A shows the box plot of the protein expressions in triplicate samples of each of primary open angle glaucoma, primary angle closure glaucoma and controls showing very little variability among the triplicate experiments. B shows the venn diagram of differential expression of proteins among glaucoma and controls while C shows the heatmap of the significantly differentially expressed proteins primarily belonging to two clusters as shown.
Figure 2

A-MTT assay of Human trabecular meshwork cells after oxidative stress with H2O2. B shows the FACS analysis of early and late apoptotic cells with C showing percentage of apoptotic cells maximum at 800uM H2O2 concentration.
Figure 3

Relative gene expression of Autophagy (A), apoptosis (B) and necrosis (C) related genes in in-vitro primary human trabecular meshwork cells after 48 hours and 72 hours of oxidative stress with H2O2. D, E- Epigenetic modifications on immunoblotting associated with moderate or severe oxidative stress in HTM.
