Abstract

Purpose: With the advent of new hepato-biliary interventions, preoperative assessment of coeliac, hepatic, and mesenteric arterial anatomy has now become a necessity for surgeons and interventional radiologists. The primary aim is to avoid or minimize the ischemic complications that could occur during surgeries such as liver transplants, abdominal interventions etc. This study was undertaken to evaluate the variants in coeliac, hepatic, and superior mesenteric arteries based on CECT abdomen.

Methods: A prospective study was conducted over a period of 2 years (2020- 2021) on 388 patients who underwent CECT abdomen for evaluation of the above-mentioned variants.

Results: 14 types of CM trunk and 11 types of hepatic artery variants were identified in this study. Anatomical variations in CM trunk and CHA were seen in 6.4 % and 7.7 % respectively. The average diameter of the coeliac artery was found to be 6.6 mm, common hepatic artery was 5.04 mm and superior mesenteric trunk was 6.6 mm.

In cases with variant coeliac -SMA axis, the average diameter of the coeliac trunk was 5.7 mm while the average arterial diameter of the hepatic artery in CHA variants was 4.38 mm.

The pathological variations found in the study were: MALS/ Dunbar syndrome, SMA compression syndrome, aortoarteritis and nutcracker syndrome.

Significant correlation was noted between presence of CHA and coeliac -SMA axis variations i.e., the patients with CHA variation were 3.38 times more likely to have coeliac-mesenteric arterial variation.

The diameters of common hepatic and coeliac artery was noted to be reduced in cases with anatomical variations (p < 0.05).

CONCLUSION - There is an association of coeliac -mesenteric artery variations with common hepatic arterial variations. Another correlation was found between the arterial diameters in cases with variant anatomy versus normal cases in the study population. No significant association between pathological variants like median arcuate ligament syndrome, SMA compression syndrome etc. with normal hepatic /CM trunk variations.

Attempt was also made to describe the newly found variations in these target vessels, not previously characterized in the standard classification system.

Introduction

A thorough knowledge of the coeliac, superior mesenteric, and inferior mesenteric arterial anatomy and its variants is vital for a successful hepatobiliary surgery. Its importance has been a topic of research since 1756 with Haller et al being the first to describe the variations in coeliac axis. Michel et al was the first to propose a
classification system for the anatomic variations in the common hepatic artery (CHA) based on cadaveric dissection(1). Suzuki et al. was the first to perform an angiographic study on hepatic arterial variations on 200 patients.(2)

The surgical relevance of the anatomy of the coeliac trunk, superior mesenteric artery (SMA) & CHA is discussed in the following section:

**SURGICAL RELEVANCE OF CHA VARIANT ANATOMY:**

Variations in hepatic arterial branching pattern create unexpected difficulties during the procedure, like trans arterial hepatic artery chemoembolization (TACE). Variants can lead to inadvertent complications like haemorrhage, improper catheter placements causing incomplete embolization of tumour or even lead to damage to the normal liver parenchyma during chemoembolization. (3)

The accessory gastric arteries which can arise from the aberrant hepatic arteries should also be considered esp. in treatment of hepatic neoplasms with TACE, as they can lead to complications like gastric perforation. This is because complications like gastric wall ischemia can arise due to obliteration of the accessory artery. In liver, reconstruction of the arteries supplying the donor liver is required before the procedure to avoid complications like arterial thrombosis. (4)

The variant anatomy can also be beneficial in some cases like in cases with replaced Right hepatic artery (RHA) which is beneficial for a donor due to its longer course, thus providing a larger graft and hence reducing complications like arterial thrombosis. (5) At the same time, this can pose a problem for the recipient liver as multiple vascular anastomoses are required between the donor and the recipient. Another added problem is the small calibre of the common hepatic artery which can lead to post op complications. (5,6)

In pancreatic surgeries e.g., pancreatic tumours resection or pancreaticoduodenectomy, presence of an aberrant right hepatic artery can lead to intraoperative vascular damage as the artery courses in close proximity to the pancreatic head (if its origin is from SMA). (7)

If the origin of the artery of the artery is from the left gastric artery (LGA), vascular injury occurs while mobilizing the stomach. Knowledge of these variants helps the surgeon to anticipate and manage the complications and determines the outcome of the surgery. An example is anticipating an anastomotic leak in a hepatobiliary surgery due to ischemia of the biliary anastomosis as the major blood supply to the extrahepatic biliary tree is from the aberrant right hepatic artery.(4)

There can also be compression of the common hepatic duct (CHD) leading to gall stone formation due to biliary stasis. (8)
In hiatal surgeries for gastroesophageal reflux disease, liver transplantation etc. there is an increased likelihood of injury to the aberrant left hepatic artery as it lies in the hepato gastric ligament which in turn can lead to left liver lobe ischemia. (4)

Variant anatomy can also prove beneficial in cases where there is occlusion in the porta, because in such cases, the aberrant left hepatic artery provides the collateral circulation. Presence of an accessory right hepatic artery can also determine the course of progression of bile duct cancer. This is because, in classic cases, bile duct cancer usually spreads to the RHA due to its close proximity. However, in patients with accessory hepatic artery, these vessels are spared as they are further apart. (9)

Knowledge of CHA variants is also important in pre surgical planning of cholecystectomy to know the laparoscopic appearance of porta hepatis. (10)

Thus, the knowledge of this variant anatomy imparts individualization of medical and surgical therapies.

**SURGICAL RELEVANCE OF COELIAC ARTERY VARIANT ANATOMY:**

The position of coeliac trunk is of immense importance to an interventional radiologist as the vertebral level serves as a landmark for the localization of its orifice, for catheter insertion, especially in cases of upper GI bleed embolization. It is also relevant in the treatment of vascular complications like pseudo aneurysms in cases of liver trauma, pancreatitis, leak from the pancreatic stump after a distal pancreatectomy or pancreatic leak following pancreateojjunostomy or pancreatogastrostomy. These procedures require selective embolization via coeliac trunk-hepatic artery catheterization, thus in turn emphasizing the knowledge of the relevant arterial variations. (11) Another situation where in coeliac trunk anatomy is of importance is in the repair of thoracoabdominal aneurysms, either through open surgery or endovascular techniques using stent prosthesis. The procedure requires cannulation of the coeliac trunk, which is then connected to an extracorporeal circulation device following which it is reimplanted in the graft, in open repair. The design of a vascular endoprosthesis for the repair of an aneurysm must consider the position of the coeliac artery and the arterial anatomy and course of its branches. (12)

**SURGICAL RELEVANCE OF SMA VARIANT ANATOMY:**

Among the SMA variations, one of the rare variations is the presence of a common coeliac –mesenteric trunk which occurs < 1% among all abdominal vascular anomalies [incidence of 0.25%]. It occurs due to the egression of the tenth root and persistence of both 13th root and anterior longitudinal anastomosis. (13) The presence of a variant like a common coeliac-mesenteric trunk will not have collateral circulation which in turn can affect the abdominal viscera (Foregut and mid gut). This can also prove a problem
during therapeutic management esp. during thrombolysis. Another vascular cause of upper abdominal angina is compression of the coeliac trunk by the diaphragmatic crura also known as median arcuate ligament syndrome or Dunbar syndrome. In patients with classical coeliac trunk anatomy, compression of the coeliac trunk alone would not present early. This is because there is reformation of collaterals between coeliac artery and SMA. However, in patients with a common CM trunk, compression of this vessel can cause decreased blood supply even to the mid gut derivatives. (5,14)

**Materials And Methods**

**SOURCE OF DATA:** The source of data for this study were the patients referred to the department of Radio diagnosis and imaging, at John's Medical College Hospital, Bangalore, for CECT abdomen. The study population was 482 patients in whom CECT abdomen was done for various indications as a part of their diagnostic workup. 94 patients were excluded from the study population as they fulfilled the exclusion criteria. The study was performed, and data was analysed for the rest of the 388 patients who satisfied the inclusion criteria.

**METHOD OF COLLECTION OF DATA:** This was a prospective study conducted over a period of two years (2020 - 2021) on patients who underwent CECT abdomen as a part of their diagnostic work up at the Department of Radio diagnosis and Imaging, St. John's Medical College Hospital, Bangalore. For the evaluation of coeliac, hepatic, and superior mesenteric arterial anatomy, CT was performed using 128 slice GE Medical Systems Revolution EVO CT scanner.

The raw imaging data obtained was then processed on a workstation for multi-planar reformation (MPR) as well as 3D reconstruction with maximum intensity projection (MIP) and volume rendering.

**INCLUSION CRITERIA**

- Patients above 18 yrs. in whom contrast enhanced CT abdomen was indicated in St. John's medical college.

**EXCLUSION CRITERIA**

- Patients in whom the CT evaluation was inadequate as a result of motion artefact/ improper breath holding technique.
- Patients who underwent major abdominal surgeries and who had a history of vascular interventions involving the coeliac /SMA/hepatic arteries.
- Patients with lesions causing derangement of the target vascular structures (i.e., hepatic, coeliac and mesenteric axis)
- Patients with atherosclerotic calcifications involving the target vascular structures.

**IMAGE INTERPRETATION AND STATISTICAL ANALYSIS:**
The coeliac trunk origin and the origin of its main branches namely the LGA, CHA and Splenic artery (SA) as well as the origin of the SMA and its branches were identified and recorded for statistical analysis to calculate the prevalence of different variants. The variants of the coeliac trunk were classified according to Uflacker's classification (TABLE 1) while the hepatic artery variants were classified depending on Michel's classification (TABLE 2).

The analysis data was done using IBM SPSS (Statistical Program for Social Science version 22.0, IBM Corp., USA). The analysis begins with descriptive analysis which includes methods such as pie diagrams, bar diagrams, histogram, and correlation. If the study data is collected from all members of the population, then these descriptive methods alone are sufficient for inferences. However, this scenario is literally impossible and estimation of population parameters using the sample population that was available for the study is needed.

Categorical variables were reported using number and percentage. Continuous variables were reported using mean +/- SD.

Comparison between variables was done by a chi square test or Fisher’s exact test for categorical variables, and an Independent T test for continuous variables (parametric) / Mann-Whitney U test with post hoc Bonferroni correction for continuous variables (non-parametric). The data normality was assessed using histograms and probability plots. Q-Q plots were used to determine if the data were normally distributed.

To compare categorized characteristics of the study population between the two groups having CHA and coeliac mesenteric axis variations, univariate comparisons were made using the Chi-square test (more than five observations in all cells) or Fisher’s exact test (five or fewer observations in one or more cells). P values for all hypotheses tested were two-sided and statistical significance was set at P < 0.05.

Results

MDCT scans were interpreted for the following:

- Presence of normal arterial anatomy (involving coeliac -mesenteric axis and common hepatic artery). In case of variant anatomy, details of origin, vascular course, co-existence of other vascular variations and pathologies were described and analysed.
- Classification of aberrant arterial anatomy variants based on standard system.
- Traditional classification for coeliac -mesenteric artery based on Uflacker's classification.
- Traditional classification for CHA based on Michel's classification.
- Separate classification of the newly found aberrant variants in both the common hepatic and CM arterial trunk.

The data collected was statistically analysed to calculate the frequency distribution of the variants. Analysis was also done to look for correlation between CHA and coeliac mesenteric variants.

Demographic data has been summarized in Table 3.

Table 3 - SAMPLE CHARACTERISTICS
Mean age of population  49.3 years
Total no. of males with mean age (SD)  191, 51 years (17.8)
Total no. of females with mean age (SD)  197, 47 years (17.9)
Previous history of surgery  19
Cases with presence of lesions causing derangement of the target vascular anatomy  42
Age group showing maximum representation  7th decade – 25.3 % percent.

COELIAC -MESENTERIC ARTERY VARIATIONS (CHART 1 AND TABLE 4):

363 out of 388 cases showed normal trifurcation pattern of the coeliac trunk (Uacker I) representing 93.5 % of the total cases. Among the commonest anomalies among the coeliac trunk variations were Type V Uacker in the form of gastro-splenic trunk with CHA arising from aorta (most common anomaly) (Figure 1) representing 20 % of cases followed by Uacker types II, III, IV & VIII (Figure 2) each type found in 4% of cases.

The variations not detected in this study population were Uacker type VI and VII.

A few other variations were found in the study population which was not previously classified. These accounted for 63 % of the total arterial variants and were classified as “Not otherwise described”. These variations are gastroduodenal artery originating from coeliac axis, origin of LHA form aorta, origin of LHA / RHA / right inferior phrenic artery from coeliac artery (Figure 3). In this category, the commonest was the origin of LHA from coeliac artery (20 % of the cases).

CHA VARIATIONS (CHART 2 and TABLE 5)

The commonest anomalous hepatic artery variation was Michel type III variation i.e., replaced right hepatic artery originating from the superior mesenteric artery which was found among 63 % of the cases. This was followed by Michel type II found in 10 % of cases. The variations not detected in this study population were type IV and Type X.

Variance in the origin of CHA was seen in 7 patients (origin of CHA from SMA in 2 and from aorta in 5 patients).

Normal origin of RHA from hepatic artery proper (HAP) was seen in 361 patients. Replaced origin of RHA was seen in 63 % of total variants (commonest variant) while accessory origin of RHA was seen in 1 (3.5%) case. Replaced LHA origin was seen in 3 (FIGURE 4) (10%) cases and accessory LHA origin in two (6.5 %) cases.

In 2 cases (8 %), the gastroduodenal artery was seen arising from the coeliac artery.
There were two cases of early bifurcation of the common hepatic artery (this was not classified as variants as it followed the classical pattern of coeliac trifurcation).

In addition, one case showed origin of the LHA from the aorta. (This was classified under the category of “Not otherwise described”: categorized under the coeliac-mesenteric axis variations).

The latter two variants have often been described as “double hepatic artery” (1).

The newly found hepatic artery variant (not described in the standard classification) was an accessory LHA (origin of LHA from LGA) along with presence of an accessory right hepatic artery (origin of RHA from SMA) (Figure 5A and 5B). This was seen in 3.5 % of the total population.

TOTAL = 388

Variations in both coeliac-mesenteric axis and hepatic artery was found in 12.6 % of the total study population.
ASSOCIATION BETWEEN CHA ANATOMICAL VARIATIONS AND COELIAC -MESENTERIC AXIS VARIATIONS:

The percentage of CHA variations having coeliac -mesenteric trunk variations was 16.7 % while the percentage of common hepatic artery variations without coeliac -mesenteric trunk variations is 6.9 %

Fischer’s exact T test was performed to analyse the presence of any correlation between coeliac-mesenteric axis and CHA variants.

The results showed significant correlation (Fischer's test statistic = 0.034) between the presence of CHA variants and coeliac mesenteric trunk variations. (a < 0.05)

The odds ratio between the 2 variables (variation in common hepatic artery & CM arterial trunk) was 3.38 indicating that the patients having CHA variations were 3.38 times more likely to have coeliac-mesenteric arterial variation.

The 95% confidence interval for the above correlation was 1.17 (lower limit)- 9.764 (upper limit) indicating that there exists a similar representative population where the patients having CHA variations were 9.76 times more likely to have a coeliac-mesenteric artery variation. (Upper limit is considered in this scenario).

ASSOCIATION BETWEEN AVERAGE DIAMETERS OF COELIAC & COMMON HEPATIC ARTERY WITH PRESENCE OF ANATOMICAL VARIATIONS (CHART 3)

The next aim of the study was to determine if there existed a significant correlation between the coeliac artery diameter in cases with Uflacker’s type I coeliac artery as compared to rest of the cases who had other coeliac artery variations.

This study also aimed to test a similar correlation between the Michel’s type I hepatic artery and rest of the CHA variants.

After assessment of the normality of the hepatic artery and coeliac artery using Q-Q plot and histogram analysis, independent T test was used to determine the equality of means.

The average diameter of the coeliac artery was found to be 6.6 mm, CHA was 5.04 mm and superior mesenteric trunk was 6.6 mm.

In case of CHA, the total number of cases with classical pattern was 358 with the average diameter of CHA being 5.09 mm.

The total number of cases with variant CHA anatomy was 30, and in these cases the CHA had a mean diameter of 4.38 mm. The mean difference between the arterial diameters while comparing both the groups (ie. Type I vs rest of the CHA variations) was 0.71 mm with a significance of 0.003 (Level of significance for the study: p < 0.05).
In the case of coeliac artery, the total number of cases with classical pattern was 363 with the average diameter being 6.72 mm. The total number of cases with variant anatomy was 25, with a mean diameter of 5.7 mm.

The mean difference between the arterial diameters while comparing both the study populations was 1.02 mm with a p value of 0.001 (Level of significance for the study: p < 0.05).

In both the scenarios, there exists a significant reduction in the average vessel diameters in CHA and coeliac trunk in patients with anatomical variations (CHART 4).

Various vascular pathologies were noted as associated findings in this study (CHART 4 and TABLE 6).

For e.g., MALS i.e., Median arcuate ligament syndrome (Dunbar syndrome). The median arcuate ligament is a fibrous arch uniting the diaphragmatic crura at the level of the aortic hiatus and passes superior to coeliac artery origin. However, if the insertion is low, it can cause abdominal pain. The diagnosis of coeliac axis compression / median arcuate ligament syndrome / Dunbar syndrome is done with conventional angiography/ CT angiography. The CECT imaging findings are characteristic focal narrowing in the proximal coeliac axis with a characteristic juxta-ostial hooked appearance with coeliac artery origin stenosis (FIGURE 6). (2)

The other pathology found in this study was SMA compression syndrome which is also known as Willkie’s syndrome/ Cast syndrome. In this pathology, there is reduced aortomesenteric angle and distance between the vessels which in turn causes compression of the third part of the duodenum.

The normal aortomesenteric angle is 45 degrees (normal range: 25° to 60°). However, in patients with significant loss of mesenteric fat, the aortomesenteric angle becomes acute (<22°) causing compression of the third part of the duodenum, thus causing resulting in SMA syndrome. (3) (FIGURE 7)

Nutcracker syndrome was another pathology found in this study which is the compression of the LRV between the aorta and (SMA). This condition is called as “anterior nutcracker syndrome.” (FIGURE ) In contrast, a circumaortic or retro aortic LRV can also be compressed between the aorta and vertebral body, which is called the “posterior nutcracker syndrome”. One of the many causes of anterior nutcracker syndrome is aberrant SMA branching from the aorta. The patient may present as a case of pelvic congestion syndrome secondary to renal venous hypertension. The imaging findings are presence of the beak sign (i.e., abrupt narrowing of the LRV between the aorta and SMA) with concomitant dilatation of the proximal LRV. Another CT parameter is a ratio of the LRV diameters at the hilar and aortomesenteric regions of more than 4.9. Few other findings include a reduced aortomesenteric angle (less than 41°) which is a very sensitive parameter/a measured beak angle of more than 32°. (4)

Table 6 - FREQUENCY ANALYSIS OF VASCULAR PATHOLOGIES INVOLVING COELIAC - MESENTERIC ARTERIAL AXIS
ASSOCIATION OF PATHOLOGICAL VARIATIONS WITH ANATOMICAL VARIATIONS:

In 6.1% of cases with anatomical variants in either coeliac-mesenteric axis variant / CHA variants or both, there were pathological variants like Dunbar / SMA compression / nutcracker syndrome.

Fischer’s exact T test was also done to look for correlation between anatomical variants and pathological conditions related to the coeliac mesenteric axis.

The Fischer’s test statistic was not significant for this association with the test statistic value of 0.092.

Discussion

Digital subtraction angiography (DSA) is the gold standard in evaluation of vascular structures esp. presence of arterial variations. However, it is invasive and is associated with iatrogenic risks and complications. (16)

These disadvantages are overcome by using CECT images for the vascular structures, which can be obtained in a high spatial and temporal resolution in a short period of time and is also noninvasive. In addition, reformats of the images can be done in coronal and sagittal planes and the post processing allows us to view only the vascular structures using minimum intensity projections. 3D reconstruction can also be performed for viewing small vessels. On account of these advantages, it has replaced the conventional angiography in assessment of the vascular structures for pre-operative evaluation of the hepatic vasculature (17).

Classification of coeliac artery variations based on its branching pattern has been performed by a number of studies, the first one done by Lipschulz in 1917 while the most recent by Uflacker in 1997 (described in Table 2) (1, 18, 19).

The classical coeliac anatomy is the type I variant which occurs at a frequency of 51–80%. Separate origin of the CHA, splenic artery, and LGA from the CA occurs in 10–19% cases while in 10%, a
quadrifurcating / pentafurcating CA is noted with the dorsal pancreatic artery, GDA, and right and left hepatic arteries originating directly from the trunk(20).

In context to the Indian population, a similar study ie MDCT evaluation of coeliac and common hepatic variations) was undertaken by Thangarajah et al in the south indian population. In comparison to the current study, no correlative analysis was performed in the mentioned study.(21)

In almost all the studies Uflacker type I (the normal trifurcation pattern of the coeliac artery) is the commonest variant which is consistent with our study. The incidence of Uflacker type I in this group was 93.5% (17) which is similar to results by the studies done by Song et al and Ugurel et al.(16, 22)

With regards to the variants (according to the Uflacker's classification), the commonest was Uflacker type V with gastro-splenic trunk and anomalies origin of the CHA from the aorta/ SMA representing 20% and this is relatively higher as compared to Ugurel et al.(22)

However, the results in this study were contradictory to studies done by Lipschutz, and Thangarajah et al, who found that Uflacker type II was the commonest variant(18, 21). In the study by Thangarajah et al, the next common variant was the presence of a hepato-mesenteric trunk and a separate gastro splenic trunk. (21)

In this study, the non-classified variations accounted for the major bulk of the anatomical CM axis variants accounting for 63% of the total cases. The commonest variation among the non-classified variations were the origin of left or right hepatic artery from coeliac axis.

Variant arterial anatomy in common hepatic artery is noted in approx. 25–30% of the population.

The incidence of aberrant right hepatics as reported in other studies was 11–26% of which replaced right hepatic arteries were seen in 3.5–21% of cases and accessory right hepatic arteries in 1–8% cases. (3)

The incidence of aberrant left hepatics as observed in other studies was 12.5–32% with accessory left hepatic arteries in 4.5–32% cases and replaced left hepatic arteries in 4-15.5% cases.(23)

With regards to the hepatic artery variations, this study showed that Michel type I is the commonest type (classical type I) with an incidence about 92.3% which is slightly higher than the prevalence of these variants in the normal population (51–80%) as reported by Kamel et al (24). With regards to the anomalous arterial variants, this study showed that Type III was the commonest anomaly with replaced RHA from the SMA representing about 63% of the total cases and these results are consistent with studies conducted by Koops et al and De Cecco et al with variable incidences (25, 26).

However, in studies by Covey, Thangarajah and Cokun et al Michel type V was the commonest variant in their study group.(3, 21, 26)

In this study, a new hepatic artery variant was found which has not been previously described. This variant was a replaced left hepatic artery from left gastric along with accessory right hepatic artery from
superior mesenteric artery which was classified as not otherwise described.

In accordance with the above-mentioned findings, this study has added 5 newly found variations to the one found by Uflacker i.e., origin of gastroduodenal artery from the coeliac artery, origin of left hepatic artery from aorta and other branches of coeliac artery together, separate origin of right hepatic artery directly from coeliac artery, separate origin of left hepatic artery from coeliac artery and aberrant origin of right inferior phrenic arising from coeliac axis. These variants were grouped into a category of not otherwise described. (Type IX)

A cadaveric study was done by Silviera et al in which the arterial diameters were compared between the groups which had normal anatomy and those who had anatomical variants. This study showed smaller diameters for variable vessels; however, the difference was not significant.(7)

In comparison, this study has a significant reduction in the coeliac artery diameter in the presence of anatomical variations. This finding can be of significance while selecting patients for liver transplantation.

A significant correlation between arterial diameter in patient groups with normal anatomy and group with common hepatic artery variations has also been established.

After extensive literature review, there was no mention of a previous study for the analysis of the above-mentioned objectives.

However, in both the above scenarios (ie. Association of arterial diameters with anatomical variation of common hepatic and coeliac-mesenteric trunk), correlation between the individual variants with the arterial diameters could not be performed as the frequency of these individual variants are less and because of the relatively smaller size of the study population. However, this is a possibility with a larger study population.

One of the ancillary findings in the study was the presence of bilateral accessory renal arteries (anatomical variant) in 3 cases with replaced right hepatic arteries.

A study by Ugurel et al showed significant correlation between anatomical variants in renal artery and coeliac trunk–hepatic arterial system variations.(22) This association was however not explored in this study.

Regarding pathological variations, no significant correlation was seen between the anatomical and pathological cases in this study.

However, previously a case report was published proposing an association between median arcuate ligament syndrome and presence of a CM trunk (Uflacker’s type VI variation).(27)

A similar theory was also proposed by Loukas et al which stated that the presence of a single trunk was one of the possible cause of MALS.(28)
The other pathology found in this study was SMA compression syndrome which is stated to have a prevalence of 0.1–0.3%. The normal SMA -aortic angle is between 25–60 degrees with an average of 45 degrees. In SMA compression syndrome, the CT criteria is the aortomesenteric angle of less than 22 degrees with a reduced aorto-mesenteric distance of 8–10 mm. There is also compression of the 3 rd segment of the duodenum with proximal dilatation of the stomach and 1st/ 2 nd parts of the duodenum. The congenital variance in the SMA origin was touted as one of the factors causing SMA compression syndrome. (29)

In this study, no coeliac -mesenteric trunk anatomical variants were noted in the cases with SMA compression syndrome.

No prior study was found exploring the correlation between aorto mesenteric angle and variants. This was attempted in this study; however no significant correlation was found.

Conclusive evidence of the same can only be provided by testing the association in a larger population.

**STUDY LIMITATIONS**

In the context of association of arterial diameters with anatomical variation of common hepatic and coeliac-mesenteric trunk, correlation between the individual variants with the arterial diameters could not be performed as the frequency of these individual variants are less and because of the relatively smaller size of the study population.

**Conclusion**

Analysis and characterization of coeliac-mesenteric trunk and hepatic artery variants is important as a part of pre-interventional/ pre-surgical workup to decrease the post-surgical complications and the morbidity rates. MDCT is a non-invasive modality which is quite efficacious in diagnosing these variants in comparison to the conventional modality of DSA.

The current study comprised of 388 patients evaluated by CECT (Revolution Evo 128 slice helical CT, GE medical systems) fat the Department of Radio diagnosis and Imaging, St. John’s Medical College Hospital, Bangalore.

CECT was assessed for the presence of anatomical variations in coeliac, mesenteric, and common hepatic arteries and comparison of this study with the standard classification proposed in literature. The assessment also included presence of vascular pathologies in these arteries, evaluation of arterial diameters, aorto-mesenteric arteries, and other associated pathologies.

The influence of age and sex in the distribution of the target arterial variant anatomy was investigated. A female predominance was seen, as was the predominance involving the seventh decade of life. Both CHA & CM arterial variations were seen predominantly in males. The classic pattern was the most common
variation found in majority of the subjects. Among the variants, Uflacker's classification Type V and Michel's classification Type III were the most common types.

In contrast to few other previous studies, which showed a higher incidence of type II variation, this study had a higher incidence of type V coeliac axis variation. Coming to CHA variants, the type III variant was the commonest which was comparable to previous studies in literature.

This study also found significant association between smaller arterial diameters and presence of variant anatomy. Another significant correlation found in the study was the linear relationship between CHA variants and coeliac-mesenteric variants. Associated findings like presence of vascular pathologies like coeliac / SMA compression syndrome, MALS etc was also analysed.

Overall, MDCT acts as an effective imaging modality in evaluation and characterization of anatomical variations of coeliac / mesenteric artery & common hepatic artery and its associated findings. Such evaluation helps not only in deciding the future course of management. But also, in reducing the associated mortality and morbidity, thus becoming vital to patient care.

Declarations

 Ethics approval – Since our study was a retrospective in nature, waiver of consent was obtained from the Institutional ethics committee (IEC). No identifiable patient data was used in the study.

 Consent to participate and Consent for publication – Not applicable

 Competing Interests – The authors have no relevant financial or non-financial interests to disclose.

 Author contributions –

 J.J. was in charge of the study idea, study design, data collection, data interpretation, manuscript writing.  

 S.R. wrote the manuscript text, prepared the tables, figures and charts and was in charge of submission of the final manuscript. A.G. helped in implementation of the study design, data interpretation, formulating inferences, revision of the manuscript and related content. N.K. contributed to data interpretation, formulating inferences, supervision of the manuscript writing and revision. B.P. supervised the entire study, revision of manuscript, tables, figures, and charts and critically revised it for important intellectual content.

 All five authors reviewed the final version of the manuscript.

 Funding - No funding was obtained for the conduction and publication of this study.

 Availability of materials and data –
The datasets generated in the current study are available and can be accessed on request from the corresponding author.

**Acknowledgements** – We would like to express our thanks and gratitude to the Department of Radiology, St. John's medical college for their everlasting support.
