Abstract

Background: Ataxia telangiectasia (A-T) is a rare autosomal-recessive multisystem disorder characterized by pronounced cerebellar ataxia, telangiectasia, cancer predisposition and altered body composition. In addition, evidence is rising for endocrine dysfunction.

Objectives: To determine the evolution of diabetes and its prevalence in a larger A-T cohort.

Methods: A retrospective analysis of the patient charts of 39 subjects from the Frankfurt A-T cohort was performed between August 2002 and 2018 concerning HbA1c and oral glucose tolerance (OGTT). The median follow-up period was 4 years (1-16 years). In addition, in 31 A-T patients aged 1 to 38 years HbA1c and fasting glucose were studied prospectively from 2018-2019.

Results: In the retrospective analysis, we could demonstrate a longitudinal increase of HbA1c. The prospective analysis showed a significant increase of HbA1c and fasting glucose with age ($r = 0.79$, $p < 0.0001$). OGTT has a good sensitivity for IR screening, whereas HbA1c can be used to evaluate individual courses and therapy response. Seven out of 39 (17.9%) patients suffered from diabetes. Metformin did not always lead to sufficient diabetes control; one patient was treated successfully with repaglinide.

Conclusion: Diabetes is a common finding in older A-T patients and often starts in puberty. Our data clearly demonstrate the need for an annual diabetes screening in patients > 12 years.

Background

Ataxia telangiectasia (A-T) is a rare autosomal-recessive multisystem disorder characterized by pronounced cerebellar ataxia, telangiectasia, cancer predisposition and altered body composition (1–3). The incidence is estimated at 1: 40,000–1: 200,000 (4).

The sequence of the *Ataxia Telangiectasia Mutated (ATM)* has been known since 1995. It is located in the region of chromosome 11q22-23 and encodes a 370 kDa protein belonging to the family of signal transduction molecules (5, 6). *ATM* encodes for a serine / threonine kinase which is activated in response to DNA double-strand breaks and has over 700 interaction partners, including the tumor suppressor p53 (7, 8). In this way, a large number of processes such as cell cycle checkpoints, DNA repair systems or apoptosis are controlled. Due to the multitude of tasks, the failure of the kinase results in a complex clinical appearance that manifests in various organ systems (9). Many of the clinical alterations observed in A-T patients may be related to the dysfunctional control of reactive oxygen species (ROS) observed when *ATM* is deficient (10, 11).

Medical care for A-T patients has improved significantly during the last years and new treatment options rise hope to patients and physicians (4). With increasing life expectancy evolving morbidities like liver disease (12), insulin resistance (IR) (13), lipid alterations (14, 15) and cardiovascular disease (16) are coming to the fore as a typical signs of premature aging (17).
While gastrointestinal involvement, mainly dysphagia, poor weight gain and failure to thrive have been characterized well (2, 3, 18–21), hepatic and metabolic disease is a new emerging disease entity (12, 15). Recently, it was shown that \( \text{ATM} \) is also involved in metabolic and cardiovascular complications when disrupted (13, 15, 22, 23). \( \text{ATM} \) is a critical player in a multitude of cellular pathways for glucose metabolism (24–26). \textit{In vitro} hyperglycemia led to increased activation of the \( \text{ATM} \) protein in pancreatic \( \beta \)-cells (27). The absence of \( \text{ATM} \) leads to dysglycemia and IR with lower Matsuda index when compared to controls while performing an oral glucose tolerance test (OGTT) (28).

\( \text{ATM} \) protein is involved in glucose transport, and lack of \( \text{ATM} \) can cause IR (24). Cytoplasmic \( \text{ATM} \) is a major upstream activator of Akt thus contributes to the translocation of cell surface glucose transporter 4 (GLUT4) to cell membrane (24). Early IR and a high prevalence of diabetes type 2 in older A-T patients as well as their family members have been described (23, 29–32). In the last years, it became evident that \( \text{ATM} \) gene polymorphisms are associated with higher risk of type 2 diabetes (33) and poorer response to metformin treatment (34).

The aim of this retrospective and in part prospective study was to evaluate our patient cohort for the incidence of IR and diabetes. In addition, we evaluated the therapy efficaciousness of diabetes treatment in seven patients.

**Methods**

Between August 2002 and August 2018 we studied data of 39 classical A-T patients from the Frankfurt A-T cohort aged 1 to 38 years regarding HbA1c and outcome of OGTT. The parameters were taken from the available patient charts. In addition, 31 A-T patients were investigated for HbA1c and fasting glucose prospectively. The parameters were determined in the serum of whole blood.

(Pre-)Diabetes was defined according to recent International Society for Pediatric and Adolescent Diabetes (ISPAD) guidelines as pathological 2 h-postchallenge glucose, fasting glucose \( \geq 126 \text{ mg/dl} \) or HbA1c \( \geq 5.7\% \) (35).

All patients were clinically and/or genetically diagnosed with A-T according to recent World Health Organization (WHO) recommendations. We compared patients \(< 12\) years of age (group 1) to patients \( \geq 12\) years (group 2).

**Data ascertainment**

The data presented were collected from two non-interventional clinical trials at the children’s hospital Frankfurt. Both trials were registered at clinicaltrials.gov 2012 (Susceptibility to infections in ataxia telangiectasia; NCT02345135) and 2017 (Susceptibility to Infections, tumor risk and liver disease in patients with ataxia telangiectasia; NCT03357978). The studies were approved by the responsible ethics committee in Frankfurt (application number 121/12 and 504/15) and conducted following the ethical principles of the Declaration of Helsinki, regulatory requirements and the code of Good Clinical Practice.

**Statistical analysis**
For statistical analysis GraphPad Prism 5.01 (GraphPad Software, Inc.) was used. Values are presented as arithmetic means with standard deviations (SDs). For comparisons between the two study groups, two-tailed Mann-Whitney-U test was applied. Correlations were analyzed by Spearman's correlation coefficient. \( P \) values \( \leq 0.05 \) were considered significant.

Results

Retrospective trial

From our data base, we collected HbA1c of 39 A-T patients who presented in our clinic within this period of time and had at least one measurement of HbA1c; a total of 73 HbA1c measurements were performed. HbA1c was significantly higher in group 2 compared to group 1 (4.85 ± 0.14% vs. 5.65 ± 0.08%, \( p < 0.0001 \)). We could show a significant correlation between age and increased HbA1c (\( r = 0.59, p < 0.0001 \)). Figure 1 shows the progression of HbA1c with age. According to our data, an annual screening from the 12th year of age is indicated for better care of A-T patients.

We evaluated the results of OGTT in 13 older patients (Median age: 17.5 years). As shown in Table 1, 7 out of 13 patients had IR or diabetes. OGTT was more sensitive to detect disturbed glucose metabolism than the corresponding HbA1c.

#diagnosed in an outpatient clinic

n.a. = not available
Seven out of 39 patients (17.9%) had diabetes, all of them were ≥ 12 years of age at diagnosis (median age at diagnosis: 21 years). Figure 2 shows OGTT results in six patients who had or developed diabetes.

**Prospective trial**: Patient characteristics are shown in Table 2. HbA1c and fasting glucose were significantly increased in group 2 compared to group 1 (HbA1c: group 1: 4.84 ± 0.35%, group 2: 5.72 ± 0.6%; p < 0.0001, fasting glucose: group 1: 84.2 ± 10.13 mg/dl, group 2: 103.7 ± 16.8 mg/dl, p < 0.0001). Pathologically increased HbA1c levels were found in 30% (3/10) of older A-T patients. We could establish a significant correlation of HbA1c (r = 0.79, p < 0.0001) and fasting glucose (r = 0.51, p < 0.001) with age. The correlations are shown in Figs. 3 and 4. 30% (3/10) of group 2 suffered from diabetes type 2 whereas no patient in group 1 was affected.

The values are shown as mean ± SD, n.s. = not significant
All diabetic patients received treatment with metformin (Table 1). Response to metformin was favorable 4/7 patients (57.1%). 2/7 patients did not respond to metformin monotherapy. Due to gastrointestinal side effects, one of these patients discontinued the metformin treatment. After a short period without any treatment, subcutaneous injections of insulin glargin were started. Still, the patient suffered from poorly controlled diabetes marked by a fasting glucose of 250 mg/dl and HbA1c of 7.6% at presentation in our clinic. Due to an advanced neurological deficit we were hesitant to initiate an intensified subcutaneous insulin therapy and therefore decided to treat him with repaglinide orally. Within 8 weeks, HbA1c dropped to 6.2%. The individual course of HbA1c of this patient is shown in Fig. 5.

Discussion

A-T is a lethal, chronic degenerative disease. Due to the improved treatment options in the recent years, hitherto largely unknown disease features such as endocrine dysfunction, liver disease and cardiovascular diseases are gaining in importance (12, 15, 36, 37). The present work clearly demonstrates the high rate of type 2 diabetes (17.9%) among post-pubertal patients.

Diabetes is one of the leading causes of death worldwide (38). It leads to a high cardiovascular risk, microangiopathy, dyslipidemia, nephropathy, neuropathy and repressed immune system (38). HbA1c values in the upper normal range indicate a high risk for later diabetes (39). In condition of A-T, IR and diabetes have rarely been investigated in clinical settings. In view of the comorbidities (e.g. malnutrition, neurological deficit and immunodeficiency), consistent diabetes therapy is of particular importance.

In the cytoplasm of the cells, ATM causes activation of the serine/threonine-specific protein kinase Akt in response to insulin. Akt is an important protein which participates in the signaling cascade for the inhibition of apoptotic signals (40). In response to insulin, protein translation is stimulated, and glucose uptake is controlled by GLUT 4 (24). In mice with a muscle-specific deletion in the \textit{GLUT 4} gene develop IR and glucose intolerance (41). Low ATM levels will therefore contribute to the development of IR and glucose intolerance in A-T via the down-regulation of Akt activity in muscle cells (24).

In 2000, the insulin signaling induced ATM-dependent phosphorylation of 4E-BP1 was reported (45). Ever since, the deficiency in the insulin and insulin-like growth factor 1 (IGF-1) axes has been demonstrated in the absence of ATM (20, 26). Apo E knockout mice without ATM protein showed increased IR and were prone to develop a metabolic syndrome (22).

Additionally, \textit{ATM} is a regulator of adipocyte differentiation. In \textit{Atm}-deficient mice lack of induction of C/EBPa and PPARγ, central transcription factors for adipocyte differentiation, as well a reduced fat mass were reported (42). Of course, fat mass is of particular importance for glucose metabolism and homeostasis. There was no significant difference when comparing fat mass of A-T patients to sex and age matched healthy controls in humans (2). Apparently, the significantly decreased lean mass is a major contributor to the disturbed glycemic control in A-T patients.

Apart from that, there have been few reports on endocrine abnormalities in A-T patients (37). While poor weight gain, stunting and delayed pubertal development have been characterized as a typical findings in A-T
(2, 3, 19, 20, 37), abnormalities in glucose metabolism are hardly described as clinical manifestation (30–32). We have recently reported about liver involvement in A-T and dyslipidemia (12). In synopsis of lipid metabolism disorder and IR, A-T patients suffer from an incomplete metabolic syndrome with increased risk for cardiovascular events (15, 16, 43).

Due to better care, life expectancy of A-T patients has emerged over the last decades (44). Especially in the light of new treatment options such as bone marrow transplantation (45–47), dexamethasone treatment (48–50) and gene therapy (51–53) disease facets with manifestation in the later disease course should be screened and treated. According to our data, diabetes screening is indicated starting for the age of 12 years. HbA1c is an easy to obtain, inexpensive marker that can be used to evaluate individual courses and therapy response. However, OGTT is more sensitive in diagnosing IR than HbA1c and fasting glucose. This shows that the OGTT is still of value and confirms the current recommendation of the English CF society: HbA1c reflects glycemic control over a period of time. This may have some advantages over the OGTT, but the use of HbA1c as a screening for CF is often within the normal range despite an OGTT diagnostic of diabetes in CF (54). Taken these information into account, we truly believe that both measurements, HbA1c and OGTT, should be applied in A-T patients.

First line treatment for insulin-resistant diabetes is metformin (38). However, to our clinical experience, not all A-T patients respond to treatment with metformin. As has been shown in 2011, inhibition of ATM in rat hepatoma cell lines diminished the effect of metformin by reduced phosphorylation and activation of AMP-activated protein kinase (25). Additionally, the gene variant SNP rs11212617 at a locus that includes the ATM was proved to influence the glycemic response to metformin in type 2 diabetes (55). In line with these studies, Connelly et al. reported that the absence of ATM leads to dysglycaemia and IR with lower Matsuda index when compared to controls while performing an OGTT (28). Nevertheless, they could not show altered fasting glucose levels, insulin concentrations or insulinogenic index measurements (28).

In addition to that, it is important to consider the general condition of the patient with particular attention to the neurological status, body composition and independence in the patients’ everyday life. For instance, subcutaneous injections often present an insurmountable barrier to self-administration due neurological impairment [unpublished clinical observation]. Apart from clinical experience, research on endocrine and metabolic alterations in A-T is rare (15, 22, 37, 56). No guidelines for treatment of diabetes in this challenging patient group are available.

In case a patient does not respond adequately to metformin therapy, insulin treatment is recommended. However, subcutaneous insulin injections are not feasible for older A-T patients with considerable neurological deficit. There is a dilemma between the autonomy of patients and the necessary treatment. To improve compliance, a different treatment regimen with oral antidiabetic drugs such as repaglinide may be used in special cases (57). In the Frankfurt A-T cohort, one of our A-T patients with diabetes had poorly controlled serum glucose levels under treatment with insulin glargin. We initiated a treatment with repaglinide. Hereunder, with a very favorable side-effect profile, a good therapeutic success and at the same time excellent compliance was achieved.
Nevertheless, the beneficial effects of insulin as anabolic hormone should be taken into consideration when escalating diabetes therapy (58). Especially in malnourished patients, an amelioration of the nutritional status with weight gain could be achieved with insulin injections. The insulin/IGF-1 axis increases muscle mass and bone density and improves insulin sensitivity as well as enhancement of free fatty acid oxidations in the muscles. Also, it was shown recently that the IGF-1 pathway has beneficial effect on cardiovascular and cerebrovascular disease (59). However, insulin as anabolic hormone and growth factor may possibly increase the cancer risk in A-T patients (60).

However, this study has some limitations. Due to the retrospective design, we cannot provide a complete data set for the diagnosis of type 2 diabetes, since many patients of our national cohort are admitted to our center for routine care annually or even every second year only. Still, to our best knowledge, this is the first prospective study on diabetes in 31 A-T patients and confirms our retrospective analysis of longitudinal data sets of our national cohort. Due to the large number of cases, we think we have delivered reliable data that clearly demonstrate the need for an annual diabetes screening in patients ≥ 12 years.

Conclusion

Especially with advancing age, a diabetes screening should be conducted regularly in A-T patients. IR and diabetes have to be treated in order to stabilize the nutritional status and avert further complications. OGTT has a good sensitivity for IR screening, whereas, HbA1c is an inexpensive marker that can be used to evaluate individual courses and therapy response. Metformin should be administered as first line treatment and in non-responders repaglinide was shown to be safe and efficacious for glycemic control.

Declarations

Ethics approval

The studies were approved by the responsible ethics committee in Frankfurt (application number 121/12 and 504/15). All patients and/or caregivers gave their written informed consent to participate in the study.

Consent for publication

Consent for publication was obtained for any individual data presented.

Availability of Data and materials

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Competing interests

The authors have no competing interest to declare.

Funding

The present study was not funded.

Authors' contributions

HD, SW, UH, SZ, RS did the study design, data collection and interpreted and did statistical analysis. MT, MK, UO, HD, SW, UH, SZ conducted visits. HD and SZ wrote the manuscript. All authors read and approved the final manuscript.
Acknowledgments

We would like to thank our patients and their families who share and support our research.
