Abstract

Background and aim: At the initial stage of the fight against COVID-19, a large number of medical staff and materials were dispatched to Wuhan City and Hubei Province to contain the outbreak quickly and effectively. The national infection prevention and control strategy posed a challenge to the physical and psychological resilience of frontline healthcare workers (HCWs) outside the central epidemic area. This study aims to survey frontline HCWs outside the central epidemic area in China to understand their levels of perceived stress, anxiety, and depression during the initial stage of the fight against the COVID-19 outbreak.

Methods: From February 11 to February 14, 2020, an online survey was conducted in Jinzhong, Shanxi Province using snowball sampling techniques. The survey consisted of two parts, namely, demographic data and psychological screening. Demographic information included gender, age, hospital classification, working department, profession type, and working experience. Perceived stress was assessed by Chinese simple Perceived Stress Scale 10, general anxiety was assessed by the General Anxiety Disorder Scale, and depression was evaluated by the Patient Health Questionnaire-9.

Results: A total of 1,315 frontline HCWs were included, of which 646 (49.1%) reported a moderate to severe stress (scores ≥ 14), 141 (10.7%) reported moderate to severe anxiety (score ≥ 10), and 164 (12.4%) reported a major depression (score ≥ 10). Female gender was significantly associated with high levels of perceived stress, anxiety, and depression ($P < 0.05$), and working time was negatively correlated with the level of perceived stress, anxiety, and depression ($P < 0.05$). Statistical difference was observed in perceived stress score among different age groups, levels of hospital group, and working departments ($P < 0.05$).

Conclusion: During the initial stage of the fight against COVID-19 in China, more than half of the frontline HCWs outside the central epidemic area rated perceived stress as moderate to severe, and nearly 23% of them reported moderate to severe anxiety or depression. Female gender, low hospital level, and emergency department were associated with a high level of perceived stress.

Introduction

Since late December 2019, many atypical pneumonia cases were reported in Wuhan, Hubei Province, China [1]. Over 57,000 confirmed cases of the novel coronavirus disease (COVID-19) in nearly 200 countries were reported in March 31, 2020, and COVID-19 has caused a large global outbreak and is now a major public health issue [2]. The COVID-19 infection outbreak is an emerging, rapidly evolving situation. The major route of transmission of the COVID-19 is droplet and close contact [3]. In the healthcare setting, certain treatments and procedures contributed to increased transmission. Healthcare workers (HCWs) are the highest risk group for infection by the COVID-19 virus [4]. In February 24, 2020, the National Health Commission of the People's Republic of China reported in the press conference of WHO-China Joint Mission on COVID-19 that 3,387 HCWs have been confirmed infected with COVID-19, with 22 (0.6%) deaths [5].

Given the increasing number of patients and suspected cases, the COVID-19 outbreak has caused public panic and mental health stress. Moreover, the increasing scope of outbreak-affected countries has generated public anxiety. The HCWs who are working under extreme stress and who are caring for infected individuals have felt scared or experienced significant psychological conflict between their duties and their concern for their own safety during the COVID-19 outbreak [6–9]. Therefore, during the outbreak, China has been handling public psychological barriers and performing psychological crisis intervention in its level-1 public health emergency responses. Surveys were conducted to determine the risk factors and the mental stress status of the general public, and members and nonmembers of medical teams aided in COVID-19 control [10–12]. However, during the fight of COVID-19 in China, nearly 30,000 medical workers were dispatched to Wuhan City and Hubei Province to address the shortage of medical workers and protective materials in the central epidemic. However, HCWs outside Wuhan City and Hubei Province may need to bear more pressure due to shortage of personal protective equipment, colleagues, and experts. Therefore, the primary objective of this study is to determine the perceived

stress and clinically significant symptoms of depression and anxiety in a large representative sample of frontline HCWs fighting COVID-19 outside Wuhan City and Hubei Province. We used three screening scales that were widely used in general psychiatric practice, namely, the Chinese simple Perceived Stress Scale 10 (C-PSS-10), the General Anxiety Disorder Scale (GAD-7) for anxiety, and the Patient Health Questionnaire-9 (PHQ-9) for depression. Our secondary goal was to identify the risk factors associated with the psychological status to determine whether intervention should be offered selectively, particularly targeted toward high-risk individuals.

Methods

Settings and participants

The study is a descriptive one. It aims to evaluate the psychological stress caused by the COVID-19 outbreak on HCWs outside the central epidemic area. To reduce the transmission possibility of face-to-face contact and communication and avoidance of large gatherings and activities, we initiated a survey using a mobile app questionnaire from February 11 to February 14, 2020. Frontline medical staff included various persons who provide medical services to suspected or confirmed COVID-19 personnel during the fight against the COVID-19 epidemic. They include nurses, physicians, and laboratory and radiology workers. The Ethics Committee of Shanghai Changhai Hospital approved the study. All participants were asked to sign a written informed consent before beginning the survey.

Survey Development

Demographic data included gender, age, education, hospital classification, and years of working, departments, and professional type. The psychometric questionnaire included two parts, namely, perceived stress screening and mental illness screening (anxiety and depression). A classic stress assessment instrument, the Chinese version of the PSS (C-PSS-10) [13], was used for perceived stress screening, whereas GAD-7 [14] and PHQ-9 [15] were used to assess anxiety and depression.

Definitions And Scores

The validity and reliability of the C-PSS-10, GAD-7, and PHQ-9 test have been confirmed previously in different studies worldwide [16–18].

The C-PSS-10 comprises 10 items, 6 negative questions (1, 2, 3, 6, 9, and 10) and 4 positive questions (4, 5, 7, and 8), in which the participants were asked to base their answers on their feelings on the last month to respond to each question fairly quickly. The item score ranged from 0 (never) to 4 (very often), resulting in a sum score range from 0 to 40. Individuals with high scores indicated high perceived stress. Scores ranging from 0 to 13 were considered low stress, 14–26 were considered moderate stress, and 27–40 were considered severe perceived stress.

The GAD-7 is a screening tool and severity measure for generalized anxiety disorder. The participants should mark the response that best applies to them over the last 14 days. The item score ranged from 0 (not at all) to 3 (nearly every day), resulting in a sum score range from 0 to 21. Scores of 5, 10, and 15 were considered the cut-off points for mild, moderate, and severe anxiety, respectively.

PHQ-9 is a self-administered version of the PRIME-MD diagnostic instrument for common mental disorders. It is used to make a tentative diagnosis of depression in at-risk populations. The participants were asked to mark the response that best applies to them over the last 7 days, and the score ranged from 0 (not at all) to 3 (nearly every day). PHQ-9 scale contained 9 items, of which 1, 4, and 9 were the core items. Any one of the core items with a score of > 1 needs attention because items 1 and 4 represent the core symptoms of depression, and item 9 indicates self-injury. A PHQ-9 score of ≥ 10 had a sensitivity of 88% and specificity of 88% for major depression.

Statistical Methods

The abnormal distributed continuous data were described as median and interquartile (IQR). Kruskal-Wallis

univariate analysis was used to test the difference of the stress, anxiety, and depression score among different groups. Categorical variables were also compared using Kruskal–Wallis univariate analysis. Correlation between demographic variates and mental impact degree was analyzed using Spearman test. All tests were two-tailed, and $P < 0.05$ indicated statistically significant. Analyses were performed using SPSS version 21.0 (IBM SPSS, New York, USA).

Results

Survey respondents

In this study, we used snowball sampling strategy to implement the online survey. We focused on recruiting frontline HCWs fighting against the COVID-19 outbreak outside the central epidemic area (i.e., Wuhan City and Hubei Province). The survey was initially disseminated to the Department of Medical Administration, Jinzhong Health Committee of Shanxi Province and was then passed to hospitals at all levels. These hospitals were designated to fight against the COVID-19 outbreak and were center for disease control and prevention.

Overall, we received 1,317 completed questionnaires, of which 2 were rejected due to age errors, and final 1,315 respondents were valid. The validity rate was 99.85%.

Demographic Characteristics Of Respondents

As shown in Table 1, the majority of the frontline HCWs were women, with median age of 37 years. Nearly half of the female HCWs were well educated (bachelor degree: 49.9%). Moreover, 97.6% (1,284/1,315) of the frontline HCWs worked in hospitals, and more than half of them worked in public hospitals (60.2%). Less than 20% of these HCWs worked in isolation wards, and most of them had been participating in the fight against the COVID-19 outbreak in fever clinics, emergency departments, and other auxiliary examination departments. In the battle against the COVID-19 outbreak, physicians and nurses accounted for more than 80%, and most of them were experienced HCWs with work time of more than 10 years.

Psychological Effect Of Covid-19 Outbreak

The psychological effect of the COVID-19 outbreak on frontline HCWs was evaluated in two aspects. The first aspect was perceived stress. The median PSS score of the frontline HCWs was 13(IQR, 9, 18), and 646(49.1%) of these HCWs reported a moderate to severe stress (score ≥ 14). Then, general anxiety and depression were evaluated using GAD-7 and PHQ-9, respectively. Of the respondents, 806(61.3%) were considered to have a normal score (score: 0–4), 368 (28%) were considered to suffer from mild anxiety (score:5–9), 74 (5.6%) were considered to suffer from moderate anxiety (score: 10–14), and 67(5.09%) were considered to suffer from severe anxiety (score: ≥ 15). For depression screening, 164(12.4%) reported a major depression (score: ≥ 10); 221(16.8%) reported at least one core item (score: > 1), of which 123(9.4%) with either item 1 or 4 (score: > 1) and 22(1.7%) with item 9 (score: > 1). Collectively, we found that during the early stage of the fight against COVID-19, most frontline HCWs outside the central epidemic area had moderate to severe perceived stress, and nearly a quarter had moderate to severe anxiety or depressive performance that deserves attention.

Demographic Variables And Perceived Stress

As shown in Table 2, female HCWs had significant higher median PSS score than male coworkers (14 vs. 12, $P = 0.000$), and female gender was positively correlated with perceived stress degree ($r = 0.097$, $P = 0.000$). The median perceived stress score of different age groups differed significantly, with the lowest median stress score in the post-70 s age group. No significant difference was observed on the median perceived stress score among HCWs working in different levels of hospitals in fighting against the COVID-19 outbreak; however, the hospital level was weakly correlated with the stress level. Nevertheless, significant differences were observed in the perceived stress scores of HCWs with different professional titles, among them nurses had the highest median score (14, IQR: 10–18). The median perceived stress scores of the physicians was significantly lower than that of the nurses; however, the proportion of reports of severe stress was significantly higher than that of nurses (4.1% vs. 1.7%, $P = 0.018$). Work experience was negatively correlated with the perceived stress degree, and experienced workers had lower median perceived stress score and reported lower proportion of moderate or severe stress.

§Correlation between demographic characteristics and perceived stress degree						

Demographic Variables And General Anxiety

For general anxiety, Table 3 shows that the median GAD-7 score of female HCWs was significantly higher than that of male HCWs. Age was significantly associated with general anxiety degree, and post-90 s HCWs had the lowest median anxiety score and the lowest proportion of reports of moderate to severe anxiety. Well-educated respondents had a significantly higher median anxiety score(3.5 vs. 2, P = 0.000). A statistical difference was observed in the median anxiety score among HCWs working in different levels of hospitals and different departments during the fight against the COVID-19 outbreak. The anxiety level of those working in isolation wards was the lowest (2, IQR: 0-7), and that of those working in the emergency department was the highest (4, IQR: 1-7).

Discussion

The COVID-19 outbreak was unique in its extremely fast transmission rate. It has brought heavy stress to frontline HCWs, especially in the early stage. In China, during the COVID-19 outbreak, many HCWs and medical protective equipment were dispatched to Wuhan City and Hubei Province to rapidly control the epidemic and address the medical shortage in the central epidemic area. A prevention strategy may increase the psychological pressure on medical staff in noncentral epidemic areas. Therefore, although different psychological effects of COVID-19 on the general public and healthcare providers have been reported [10-12], the present work focuses on the psychological status of frontline HCWs working outside the central epidemic area during the initial stage of the fight against COVID-19 in China. The results showed that more than half of the frontline HCWs working outside central epidemic area faced moderate to severe perceived stress, and

approximately 23% of them could even be diagnosed with moderate to severe anxiety or major depression. In addition, we found that some demographic data (e.g., female gender) were associated with a high perceived stress. To the best of our knowledge, this study is the first to assess the psychological effect of the COVID-19 outbreak on frontline HCWs fighting against COVID-19 outside the central epidemic area.

Data from the present study showed that female HCWs suffered a greater psychological effect of the COVID-19 outbreak and higher levels of stress, general anxiety, and depression compared with male HCWs. This finding corresponds to previous studies of immediate psychological response of general population on the COVID-19 outbreak during early stage in China [12] and extensive epidemiological studies that found that women are at high risk of depression [19]. Age was another social factor beyond gender that was clearly related to the mental stress of the frontline HCWs during the early stage of the fight against COVID-19 in China. Age was negatively associated with perceived stress levels, but positively correlated with anxiety levels. The reason for this finding can be attributed to young medical workers, especially the post-90s generation, mostly having little work experience and are facing public health events, such as the COVID-19, for the first time in their career. Therefore, health authorities should conduct psychological counseling for these high-risk groups early to relieve their perceived pressure, thereby reducing the rate of work errors due to psychological stress.

The analysis results showed that the general anxiety level of HCWs in the emergency department was significantly higher than that of HCWs in isolate wards or fever clinics. This notion may be due to the fact that HCWs working in isolated wards and fever clinics are voluntarily selected and have sufficient psychological preparation. Moreover, the isolated ward staff comprises of middle-level backbone with rich working experience and strong psychological tolerance. Isolation ward have the best protection facilities and technical guarantee. Furthermore, the isolation ward staff is more knowledgeable about the epidemic than their general emergency colleagues. Therefore, nonisolated wards and outpatient clinic staff must perform outbreak prevention and control skills training and psychological intervention.

Although the work of different professional staff is equally important in fighting the epidemic, the difference in their composition makes them differently stressed during COVID-19 outbreak. The results of this study indicated that compared to physicians, nurses had obviously higher perceived stress. The difference may be due to more opportunities for nurses to be exposed to the secretions and blood of patients with COVID-19, and the unit work time is longer. This result may also be related to the fact that in China, nurses are mainly female and are generally younger than physicians; thus, they have less stress resistance.

This study has several limitations. First, given the limitation of the conditions during the epidemic, we only selected the frontline medical staff in one region for investigation, which may not be able to completely represent the mental state of all frontline medical staff. Second, we could not conduct targeted interventions for these persons nor perform a comparative study of the psychological state of these populations before and after a period due to the ethical requirements on anonymity and confidentiality. Finally, we only evaluated the mental state of frontline staff in noncentral epidemic areas and did not compare with central and other staff. Therefore, a comparative study of the mental status of frontline and nonfrontline workers in different epidemic-resistant areas must be performed in the future to provide suggestions for the development of psychological intervention strategies when during public health emergencies.

In summary, the result suggested that during the initial stage of fighting against COVID-19 outside the central epidemic area in China, more than half of the frontline HCWs suffered moderate to severe perceived stress, and nearly 23% of them reported moderate to severe anxiety or depression. Female gender, low hospital level, and emergency department were associated with a high level of perceived stress. Nurses also had a higher perceived stress than that of physician colleagues.
