Abstract

Children's eating behaviors, body shape and body image cognition may be more susceptible to the influence of their parents, but these influences may be weakened with age. There may be different association pathways between parental pressure on children's body image (PPCBI), body mass index (BMI), body image dissatisfaction (BID) and eating disorders (EDs) among children and adolescents at different developmental stages. This study aims to analyze the association pathways between PPCBI, BMI, BID and EDs among children and adolescents at different developmental stages. The stratified cluster sampling method was used to select 486 students aged 8–15 years in two 9-year schools. Children's body height, weight, testicular volume and breast development were measured. PPCBI, BID, and EDs were investigated using the Appearance-related Social Stress Questionnaire, Body Size Questionnaire (BID-14), and EDI-1 scale, respectively. The boys with testicular volume <4 ml had significantly higher EDs score than girls with breast development <Tanner II ($P<0.05$). There were significant association pathways of PPCBI→BMI→BID→EDs and PPCBI→BID→EDs in boys with testicular volume <4 ml ($\beta=0.035$, $P<0.01$; $\beta=0.059$, $P<0.01$), boys with testicular volume ≥4 ml ($\beta=0.032$, $P<0.01$; $\beta=0.175$, $P<0.001$), and girls with breast development ≥Tanner II ($\beta=0.026$, $P<0.01$; $\beta=0.172$, $P<0.001$). There was a positive association pathway of PPCBI→EDs in boys with testicular volume <4 ml ($\beta=0.30$, $P<0.001$) and PPCBI→BID→EDs in girls with breast development <Tanner II ($\beta=0.176$, $P<0.01$). Parental pressure on children's body image may positively predict children's eating disorders through BMI and body image dissatisfaction in boys and girls after puberty initiation and directly predict eating disorders in boys before puberty initiation; however, it indirectly predicts eating disorders only through BID in girls before puberty initiation.

Introduction

Eating disorders, mainly manifested by abnormal eating and weight control, are prevalent among children and adolescents. An EDs is an important risk factor for nutritional intake and physical and mental development in children themselves and in adulthood. In a recent Australian survey of children aged 5–13 years, the minimum prevalence of EDs was found to be approximately 2.79/100,000 per year, and the prevalence of EDs in children has nearly doubled in the last 10 years, with a higher rate in younger boys than girls [1]. A longitudinal study showed that the symptoms of EDs were most common between the ages of 12 and 15 years [2]. The excessive expectation of weight loss, unhealthy weight control behaviors, and body image dissatisfaction are major risk factors for EDs [3]. Parental pressure on the children's body image often influences the children's self-image attitudes and changes in the children's weight [4, 5], and may also promote the development of EDs symptoms in children [6, 7]. A study suggests that childhood EDs may progress to more severe EDs in mid-adolescence or adulthood symptoms [8], and cause additional psychological distress and physical illness [9, 10]. This finding reveals that the correlation pathways PPCBI, BMI, BID, and EDs play an important role in promoting children's healthy eating behavior.
Body image (BI) is a subjective impression of the body portrayed by individuals or others [11]. With the popularity of “thin for beauty” and sociocultural pressure on body image and appearance, a BMI that is too high or too low is the direct cause of BID, which will also directly affect the development of EDs [12–16]. Deborah et al. reported that paying too much attention to weight or body shape not only caused serious psychological distress but also promoted binge eating and dieting behaviors in children [17]. Adolescent girls with a higher body mass index (BMI) who desire to lose weight and boys who prefer to increase their physical strength appear to be at greater risk for eating disorders [18, 19]. The development of children's bodies before puberty is steadily increasing, while that after puberty is rapidly increasing. Body dissatisfaction occurs relatively infrequently in prepubertal children[20], and increases with age in boys and girls[21]. From early adolescence onwards, dietary restrictions and dieting are more likely to occur due to the increasing emphasis on physical appearance and weight problems [21, 22]. Therefore, there may be different association pathways between BMI, BID, and EDs among children at different developmental stages.

Parents play an integral role in the child's body shape development and positive or negative body image cognitive attitudes [23–25]. Duchin et al. [26] reported that parents expected their children to be thinner, and their children tended to have larger body sizes or higher BMIs. Parents who teased their children about their body image or commented on their child's body shape put great pressure on children's appearance [27]. Parental pressure on children's appearance has a direct impact on children's eating behaviors, such as reducing or restricting the frequency of unhealthy eating behaviors [28, 29]. As the autonomous behavior of young children is relatively weak, their eating behaviors, body shape, and body image cognition may be more susceptible to the influence of their parents, but the influence may be weakened as children' age. There also may be different association pathways between PPCBI, BMI, and BID among children at different developmental stages. In addition, eating disorders in prepubertal children are more likely to be accompanied by a shorter duration of weight loss[30]. With the onset of puberty, children undergo dramatic changes in their physical as well as social perceptions. There are more reports of stress from parents about their body image and eating disorders among adolescents[31]. Eating disorders also increase from early adolescence, usually peaking in late adolescence[32], and Abebe et al. showed that with increased self-perceptions, children tend to develop in conflict with their ideal body image during adolescence, and girls are more likely to show binge eating symptoms in early[33]. Therefore, the purpose of this study was to analyze the different relationship pathways between PPCBI, BMI, BID and EDs to provide a theoretical basis for preventing the occurrence of eating disorders in Chinese children and adolescents with different developmental stages.

Methods

Participants

A stratified cluster random sampling method was used to select students aged 8–15 years in two 9-year schools as participants. A total of 486 students, including 262 (54%) boys and 224 (46%) girls, were recruited. The study was approved by the Medical Ethics Committee of Bengbu Medical College [(2015)
003] and conducted in accordance with the Declaration of Helsinki. The guardians of the participants signed the informed consent form.

**Procedure And Measures**

Body height, weight and secondary sex index were measured by medical personnel who received standardized training. A mechanical height meter was used to measure body height with an accuracy of 0.1 cm. The weight is measured using an electronic scale, and the counting is accurate to 0.1 kg. Boys' testicular volume was measured using a Prader testicular volume meter[34]. Girls' breast development was examined according to Tanner staging [35]. The pubertal developmental stages were divided into two stages (boys before puberty initiation: boys' testicular volume < 4 ml, boys after puberty initiation: boys' testicular volume ≥ 4 ml; girls before puberty initiation: girls' breast development < Tanner II, girls after puberty initiation: girls' breast development ≥ Tanner II).

The Eating Disorders Inventory (EDI-1) [36] was developed by Garner in 1983. In this study, the Chinese version of EDI-1 was used to survey children's EDs [37]. There are 64 items on the EDI-1 scale, and each item is scored 1–6 point from never to always. A higher score indicates a more serious eating disorder. The Cronbach's coefficient was 0.944, which indicates that the EDI-1 scale has good reliability.

In this study, the parental pressure subscale in the Appearance-Related Social Pressure Questionnaire [38] was used to assess parental pressure on children's body image. The parental pressure subscale includes 16 items, and each item is scored on a 1–5 point scale. Higher total scores indicate greater parental pressure on children's body image. The Cronbach's coefficient was a coefficient of 0.902, which indicates that the parental pressure subscale has good reliability.

The short version of the body shape questionnaire (BSQ-14) [39] was used survey children's body image dissatisfaction. The BSQ-14 scale includes a total of 14 questions, and each question is scored on a 1–6 point scale from never to always. Higher total scores represent greater body image dissatisfaction. The Cronbach's coefficient was a coefficient of 0.933, which indicates that the body shape questionnaire has good reliability.

**Data Analyses**

IBM SPSS 23.0 software was used to analyze the data. Quantitative data were described as the mean ± SD. t tests were used to compare differences in PPCBI, BMI, BID and EDs scores between boys and girls at different developmental stages. Pearson's correlation and multiple linear regression were used to analyze correlations between PPCBI, BMI, BID and EDs. AMOS 24.0 was used to construct an association pathway among PPCBI, BMI, BID and EDs, and the bootstrap procedure was used to test for direct and indirect effects. $P<0.05$ was considered statistically significant.

**Results**
A total of 486 children were validly surveyed in this study, including 168 children with prepuberty initiation (115 boys, 53 girls) and 318 children after puberty initiation (147 boys, 171 girls). Boys before puberty initiation had higher eating disorder score than girls before puberty initiation ($P < 0.05$); however, there was no statistically significant difference between the eating disorder score between boys after puberty initiation and girls after puberty initiation ($P > 0.05$), between boys before puberty initiation and boys after puberty initiation ($P > 0.05$), or between girls before puberty initiation and girls after puberty initiation ($P > 0.05$). See Fig. 1 for details.

In boys before puberty initiation, the PPCBI score, BMI and BID score were significantly positively correlated with the EDs score ($P < 0.05$), and BMI, the PPCBI score, and the BID score were positively correlated with each other ($P < 0.05$). In girls before puberty initiation, the BID score was positively correlated with the EDs score, BMI, and PPCBI score ($P < 0.05$). In boys after puberty initiation, the BID score was positively associated with the EDs score, BMI, and PPCBI score ($P < 0.05$), and BM was positively associated with the PPCBI score ($P < 0.05$). In girls after puberty initiation, PPCBI and BID scores were positively correlated with the EDs score ($P < 0.05$), and BMI, the PPCBI score and the BID score were positively correlated with each other ($P < 0.05$). See Table 1 for details.

PPCBI Parental pressure on children's body image, BID Body image dissatisfaction, BMI Body mass index, EDs Eating disorders. * P < 0.05, ** P < 0.01.

- After adjusting for age, PPCBI score, BMI, BID score and EDs score as dependent variables, and the variables associated with them as independent variables, multiple linear regression was conducted to analyze their associations (See Table 2 for details).
In boys before puberty initiation, the PPCBI and BID scores were positively associated with the EDs score ($P<0.05$); the PPCBI score was positively associated with BMI and the BID score ($P<0.05$); and BMI was positively associated with the BID score ($P<0.05$). In girls before puberty initiation, the BID score was positively associated with the EDs score ($P<0.05$); and the PPCBI score was positively associated with the BID score ($P<0.001$). In boys and girls after puberty initiation, the BID score was positively associated with the EDs score ($P<0.001$); the PPCBI score was positively associated with BMI and the BID score ($P<0.05$); and BMI was positively associated with the BID score ($P<0.01$). Therefore, there may be association pathways between PPCBI, BMI, BID and EDs, as shown in Fig. 2.

In boys before puberty initiation, the PPCBI and BID score positively predicted the EDs score ($\beta = 0.30, P < 0.001; \beta = 0.23, P < 0.05$); the PPCBI score and BMI positively predicted the BID score ($\beta = 0.25, P < 0.01; \beta = 0.38, P < 0.01$); and the PPCBI score positively predicted BMI ($\beta = 0.38, P < 0.001$). Moreover, indirect association pathways of PPCBI→BMI→BID→EDs and PPCBI→BID→EDs were statistically significant ($\beta = 0.035, P < 0.01; \beta = 0.059, P < 0.01$).

In girls before puberty initiation, the BID score positively predicted the EDs score ($\beta = 0.34, P < 0.01$); and the PPCBI score positively predicted the BID score ($\beta = 0.52, P < 0.001$). The indirect association pathway of PPCBI→BID→EDs was statistically significant ($\beta = 0.176, P < 0.01$).

In boys after puberty initiation, the BID score positively predicted the EDs score ($\beta = 0.45, P < 0.01$); the PPCBI score and BMI positively predicted the BID score ($\beta = 0.39, P < 0.001; \beta = 0.36, P < 0.001$); and the PPCBI score positively predicted BMI ($\beta = 0.20, P < 0.05$). The indirect pathways of PPCBI→BMI→BID→EDs and PPCBI→BID→EDs were statistically significant ($\beta = 0.032, P < 0.01; \beta = 0.175, P < 0.001$).

In girls after puberty initiation, the BID score positively predicted the EDs score ($\beta = 0.38, P < 0.001$); the PPCBI score and BMI positively predicted the BID score ($\beta = 0.46, P < 0.001; \beta = 0.32, P < 0.001$); and the PPCBI score positively predicted BMI ($\beta = 0.22, P < 0.01$). The indirect association pathways of PPCBI→BMI→BID→EDs and PPCBI→BID→EDs were statistically significant ($\beta = 0.026, P < 0.01; \beta = 0.172, P < 0.001$). The direct and indirect coefficients of association pathways were shown in Fig. 3 and Table 4.

PPCBI Parental pressure on children's body image, BID Body image dissatisfaction, BMI Body mass index, EDs Eating disorders.

**Discussion**

With the widespread prevalence of unhealthy eating behaviors among children and adolescents, their healthy eating has received more attention. In this study, we found that parental pressure on children's body image through child BMI and body image dissatisfaction positively predicted eating disorders in boys before puberty and after puberty initiation and girls after puberty initiation; however, only child BID positively predicted eating disorders in girls before puberty initiation.

This study found that the eating disorders score in boys before puberty initiation was significantly higher than that in girls before puberty initiation, which showed that eating disorders in boys before puberty initiation were more serious than that of girls before puberty initiation. Although many scholars report that girls account for a greater prevalence of eating disorders [40, 41], eating disorders seem to have a more serious impact on boys. Research shows that boys with anorexia nervosa presented a higher standardized mortality rate than girls [42]. Pinhas et al. [43] also reported more signs of growth retardation in boys aged 5–12 years with eating disorders, which may be associated with boys showing less needing to seek treatment [44]. Solano et al.[45] found that boys pay more attention to their parents’ perceptions of their body image. Parents play a significant role in boys’ emotional regulation [46]. Therefore, appearance pressure from parents is more likely to aggravate the symptoms of eating disorders in boys. The study also found that prepubertal boys were not as good as girls in regulating
emotional strategies [47], which may result in boys at this stage of development having a greater psychological burden than girls when dealing with eating disorders. This may be an important reason why boys before puberty initiation showed higher eating disorder scores than girls before puberty initiation.

Based on the correlation analysis and multiple linear regression analysis, we fitted the relationship pathways between parental pressure on children's body image, BMI, body image dissatisfaction, and eating disorders. The present study showed that parental pressure on children's body image positively predicted eating disorders through body image dissatisfaction in boys before puberty initiation and in boys and girls after puberty initiation. Studies have shown that parents, peers, and media influence children's negative body image perceptions, such as fear of weight gain and body image dissatisfaction[48, 49]. Parents' negative comments (such as blaming and teasing) on children's weight or body shape will cause psychological distress and may promote the development of anxiety, depression and eating disorders[4, 50]. A meta-analysis found that parents' encouragement of children to lose weight and negative comments about their weight or body shape were associated with children's body image dissatisfaction and eating disorders [51]. Negative comments on weight, body shape or eating behaviors seem to be common, with more negative information coming from mothers than from fathers [52, 53]. Therefore, parental pressure on children's appearance and eating behaviors plays an impact role in children's eating disorders.

Furthermore, the results of this study showed that body mass index positively predicted eating disorders through body image dissatisfaction. There is a consensus that overweight and obese children have greater body dissatisfaction [54]. Most children with eating disorders also expressed dissatisfaction with their body image [55]. In this study, parental pressure on children's body image also influenced children's BMI, which may be related to parenting styles. For example, parents who are aware that their children are overweight or obese are more likely to try to control eating behaviors or encourage exercise to change their child's weight [56, 57].

We also found that parental pressure on children's body image directly and positively predicted eating disorders in boys before puberty initiation and indirectly and positively predicted eating disorders through BID in girls before puberty initiation. As we mentioned earlier, prepubertal boys are less able than girls to regulate their emotions [47]. Some intervention studies on eating disorders have found that the intervention effect of parents is more significant in young children [58, 59], which suggests that the dietary behavior of young boys may be more affected by their parents. This is probably because parental pressure on children's body image in boys before puberty initiation is also directly and positively associated with childhood eating disorders and does not manifest in children in late adolescence. Handford et al. showed that negative comments from parents about children's appearance were associated with body image dissatisfaction in preadolescent girls [60]. Studies have found that girls aged 3 to 6 years pay more attention to their body parts, such as the abdomen and legs [61, 62], and preschool girls also highlight concerns about their appearance, especially clothes and hair [63]. Therefore, girls at this age may be more concerned with the evaluation of their body parts and appearance from others,
diminishing the influence of weight on them. However, as girls age, dissatisfaction with both appearance and weight becomes more prominent in adolescent girls [64]. This may explain why parental body image pressure on prepubertal girls was positively associated with childhood eating disorders only through childhood body image dissatisfaction, whereas postpubertal girls demonstrated the effect of both body image dissatisfaction and BMI on eating disorders.

There are some limitations in the study. First, this cross-sectional study has limitations in explaining causality, and the study found that the relationship pathways need further prospective research verification. Second, there are numerous factors influencing children's eating disorders, such as peer pressure, media messages, and psychological disorders, such as anxiety and depression, which were not considered in this study. Third, the current findings are only based on Chinese children and adolescents, which may limit their applicability to children and adolescents in other cultural contexts.

**Conclusions**

The present study found that parental pressure on children's body image predicted children's body mass index and body image dissatisfaction and, through them, predicted children's eating disorders. Parental pressure on children's body image also directly predicted children's eating disorders in boys before puberty initiation, while parental pressure on children's body image was only associated with children's eating disorders through children's body image dissatisfaction in girls before the onset of puberty. Parental pressure on children's body image may play an important role in the development of positive body image perceptions and prevention of childhood eating disorders, and parents should be guided to correctly perceive children's body image.

**Abbreviations**

PPCBI: parental pressure on children's body image; BMI: body mass index; BID: body image dissatisfaction; EDs: eating disorders; X2/DF: chi-square/free ratio; GFI: goodness-of-fit index; AGFI: adjusted goodness-of-fit index; SRMR: standardized root mean square residual; NFI: standard fit index; TLI: Tucker-Lewis index; CFI: comparative fit index.

**Declarations**

Acknowledgments We would like to thank the teachers and students who participated in this study, as well as all other members for their support during the different phases of the study.

Author contributions JC: conceptualization, formal analysis, methodology, drafting-initial manuscript. KL, JZ, SL: methodology, analysis, writing – review & editing. YW, RC, XP: analysis, writing – review & editing. MH, HH, RY: writing - review & editing, visualization. LF: investigation, methodology, supervision, validation, writing – review & editing. All authors have read and approved the final manuscript.
Funding  This work was supported by the National Natural Science Foundation of China (Grant Number [81502823]) and 512 Talent Cultivation Plan of Bengbu Medical College (Grant Number [by51201204]).

Data availability  The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

Conflict of interest  The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Ethical approval and consent to participate  This study was approved by the Medical Ethics Committee of Bengbu Medical College ((Ethics Approval Number: 2015 No. 003). Written informed consent to participate in this study was provided by the participants’ legal guardian/next of kin.
