Abstract

Background

Primary hypothyroidism is a known risk factor for pituitary hyperplasia, which develops symptoms due to compression of the optic chiasm and increased intracranial pressure. As pituitary hyperplasia is known to improve after levothyroxine replacement therapy, there have been no reports of a long clinical course of pituitary hyperplasia due to primary hypothyroidism.

Case presentation

An 18-year-old female presented with headache, double vision and bitemporal hemianopia. A large suprasellar tumor measuring 19.2X13.67X18.96 mm on MRI and the biological testing comprising low thyroid hormone and high TSH levels, and positive thyroid stimulation blocking antibody (TSBAb) were indicative of pituitary hyperplasia due to primary hypothyroidism with TSBAb. For the purpose of ruling out invasive pituitary tumors, the lower one-fourth of the pituitary gland was biopsied and histopathological examination showed pituitary hyperplasia and no malignant findings. A follow-up MRI showed dramatic shrinkage of the pituitary gland after levothyroxine replacement therapy. As pituitary gland size was monitored for approximately 16 years, it did not converge to a normal size.

Conclusions

We describe a case of follow-up over 16 years for pathologically diagnosed pituitary hyperplasia due to primary hypothyroidism with positive TSBAb. Repeated enlargement and shrinkage were confirmed, but observations also suggested the pituitary gland to not always return to normal size after the appearance of profound pituitary hyperplasia. The patient’s non-adherence with levothyroxine intake is likely to cause a profound pituitary enlargement, leading to symptoms due to compression of the optic chiasm and increased intracranial pressure. In the case of poor medication adherence, medication guidance is important to be provided assiduously for the prevention of profound pituitary hyperplasia, while using TSH and PRL levels as indicators.

Background

Primary hypothyroidism leads to pituitary hyperplasia via loss of negative feedback. Low thyroid hormone levels cause excess production of thyroid stimulating hormone (TSH)-releasing hormone (TRH) from the hypothalamus. Excess TRH is thought to stimulate thyrotrophs and promote their proliferation, leading to pituitary hyperplasia [1]. Pituitary hyperplasia occurs under various physiological and pathological conditions and is common in clinical practice [2–5]. The incidence of pituitary hyperplasia due to hypothyroidism has been reported to range from 25–81% [6]. It is typically diagnosed through imaging, and can occasionally be difficult to differentiate from TSH-producing adenomas on computed
tomography (CT) or magnetic resonance imaging (MRI). In addition, pituitary hyperplasia is often diagnosed based on thyroid function and clinical course after thyroid hormone replacement therapy [7].

We herein report a case of pathologically diagnosed pituitary hyperplasia due to primary hypothyroidism with positive thyroid stimulation blocking antibody. In daily practice, we encountered an 18-year-old woman with suspected pituitary apoplexy. A follow-up MRI showed dramatic shrinkage of the pituitary gland after levothyroxine replacement therapy. Thyroid function and pituitary gland size were monitored for approximately 16 years.

**Case Presentation**

An 18-year-old female experienced headache, double vision, and bitemporal hemianopia and was transported to our hospital in an ambulance. She had no past medical history. A large suprasellar tumor measuring 19.2×13.67×18.96 mm and compressing the optic chiasma was detected on MRI, and pituitary apoplexy was suspected. Hemorrhage in the tumor was not confirmed (Fig. 1). She was transferred to Hiroshima University Hospital for the purpose of neurosurgical scrutiny. On questioning, she gave a history of weight gain and constipation. She had delayed deep tendon reflexes, dry skin, and lower leg edema. Her serum levels of TSH and prolactin (PRL) were elevated to 844.5 µIU/mL (normal range: 0.31–3.15 µIU/mL) and 80.8 ng/mL (normal range: 0.0-26.3 ng/mL), respectively, whereas free triiodothyronine (FT3) and free thyroxine (FT4) levels were reduced (<0.7 pg/mL and 0.1 ng/dL, respectively). Other laboratory evaluations showed cortisol at 9.3 µg/dL, adrenocorticotropic hormone (ACTH) 13.4 pg/mL, luteinizing hormone (LH) 0.3 mIU/mL, follicle stimulating hormone (FSH) 4.5 mIU/mL, estradiol 304 pg/mL, growth hormone (GH) 0.55 ng/mL, thyroglobulin 39.3 ng/mL, thyrotropin receptor antibody (TRAb) 1.5 IU/L, and thyroid stimulation blocking antibody (TSBAb) 83.7%. Later examination revealed anti-thyroid peroxidase antibody (TPOAb) to be 93.1 IU/mL, and anti-thyroglobulin antibody (TgAb) 50.8 IU/mL.

Following her imaging and endocrine data, pituitary hyperplasia due to primary hypothyroidism was diagnosed clinically and levothyroxine replacement therapy was started (50 µg/day). The loading dose was increased to 200 µg/day. Twelve days later, a repeat MRI showed shrinkage of the pituitary gland, to 19.08×12.20×16.71 mm, which decreased the compression of the optic chiasma; thyroid function laboratory data was also improved with a TSH of 341.3 µIU/mL, FT3 of 1.9 pg/mL, and FT4 of 0.9 ng/dL. By three months after visiting our hospital, subjective symptoms such as headache, double vision, and bitemporal hemianopia disappeared. Follow-up MRI revealed little change in the tumor size, at 19.63×12.43×15.71 mm.

For the purpose of ruling out invasive pituitary tumors, the lower one-fourth of the pituitary gland was biopsied by a transsphenoidal endoscopic approach. Histopathological examination showed pituitary hyperplasia. Small acinar proliferation of anterior pituitary cells was evident, dominated by chromophobe epithelioid cells. The specimens showed an absence of nuclear mitoses and necrosis, and the reticulin acinar pattern was preserved. Immunohistochemically, most cells were positive for TSH and negative for
Ki-67 (Fig. 2). The results of the insulin, TRH, and LH releasing hormone (LHRH) loading tests performed after endoscopic biopsy are shown in Table 1. Pituitary dysfunction was not observed. The levothyroxine loading dose was gradually increased to 150 µg/day. After ten months of levothyroxine replacement therapy, a follow-up MRI showed dramatic pituitary shrinkage of approximately 50% to a tumor size of 16.79×11.28×12.59 mm, although this size was influenced by biopsy (Fig. 1). Laboratory evaluation also showed further improvement in thyroid function with a TSH of 34.68 µIU/mL, FT3 of 2.1 pg/mL, and FT4 of 0.9 ng/dL.

Afterwards, oral levothyroxine was continued. The prescribed dose of levothyroxine during a clinical course of approximately 16 years is shown in Fig. 3. However, the patient often forgot to take her medication; as such, the actual oral dose is uncertain. Thyroid function deteriorated many times over the clinical course. At each time point, the patient was found in the medical interview to not be taking her levothyroxine tablets and was urged to improve her medication adherence.

Nine years after her initial presentation, the patient came to visit our hospital of her accord. At the time of our consultation, her thyroid function was well controlled with a TSH of 0.25 µIU/mL, FT3 of 3.39 pg/mL, and FT4 of 1.54 ng/dL under a loading dose of 150 µg/day. Follow-up MRI of the pituitary also showed a decrease in height with no change in the width and length, dimensions 16.67×11.19×9.64 mm (Fig. 3). Ultrasonographic findings of the thyroid gland revealed a remarkable shrinkage and irregular surface and heterogeneous low-level internal echoes without high Doppler blood flow, compatible with autoimmune atrophic thyroiditis due to TSBAb (Fig. 4). Subsequently, the size of the pituitary was evaluated by MRI once a year. Reversible pituitary enlargement was shown, although transient changes in thyroid function had no correlation with pituitary gland size (Fig. 3). In the clinical course, there was correlation between TSH and PRL levels (Fig. 5). At approximately 16 years after the initiation of levothyroxine replacement therapy, the patient had no symptoms associated with pituitary hyperplasia, including headache and visual field disorder.

**Discussion And Conclusions**

Over approximately 16 years, we followed thyroid-related hormones and pituitary size in a patient with a definitive diagnosis of pituitary hyperplasia due to primary hypothyroidism with positive thyroid stimulation blocking antibody. To the best of our knowledge, there has not been any report describing a long clinical course of pituitary hyperplasia due to primary hypothyroidism diagnosed by pituitary biopsy findings. This case shows that although pituitary gland volume is known to decrease after levothyroxine replacement therapy, the pituitary gland may not return to normal size after the appearance of profound pituitary hyperplasia.

A previous observational study reported a correlation between serum TSH level and the frequency of pituitary enlargement. Specifically, pituitary enlargement was observed in 70% of patients with TSH levels greater than 50 µIU/mL and in 84% with TSH levels greater than 100 µIU/mL [6]. In addition, pituitary volume in patients with PRL-producing pituitary adenomas is generally known to correlate with serum
PRL level [8]. To the best of our knowledge, there is no known correlation between pituitary volume and serum TSH level in patients with pituitary hyperplasia due to hypothyroidism. In our case, such correlation was also not observed (Fig. 3). TSH is regulated by TRH stimulation in the hypothalamus-pituitary-thyroid axis; accordingly, serum TSH levels are thought to be associated not only with pituitary volume but also with factors including TRH level in the pituitary portal vein, oral dose of levothyroxine, and the percentage of thyrotrophs with high TSH secretion ability among all adenohypophysis cells.

In our case, no symptoms associated with pituitary enlargement were confirmed during the clinical course after levothyroxine replacement therapy. However, the repeated enlargement and shrinkage of the pituitary gland means that the occasional lack of levothyroxine intake exacerbated pituitary enlargement. The patient's medication non-adherence makes it difficult to accurately assess the actual dose by medical interview alone. It is important to regularly evaluate thyroid function in addition to performing imaging tests in the clinical course of pituitary hyperplasia due to primary hypothyroidism. Given that longstanding TRH stimulation causes pituitary hyperplasia, TRH measurement is important for controlling pituitary volume; however, it is difficult to acquire. TSH and PRL levels can be latent indicators for controlling pituitary volume because they are downstream of TRH. Therefore, serum TSH and PRL levels are thought to help in determining an appropriate daily oral dose of thyroid hormone.

There are two types of autoimmune thyroiditis, autoimmune goitrous Hashimoto's thyroiditis and autoimmune atrophic thyroiditis [9]. Some patients with atrophic thyroiditis are confirmed to produce TSBAb, which causes hypothyroidism due to TSH resistance via inhibition of the TSH-stimulated cAMP response [10]. Low uptake of $^{123}$I has been reported in patients with primary hypothyroidism accompanied by TSBAb and Graves' disease for whom the hypothyroidism developed after the appearance of TSBAb [11, 12]. In our case, TSBAb activity was high in addition to primary hypothyroidism. Low levels of FT3 and FT4 increase TRH secretion from the hypothalamus via a loss of negative feedback. Excess TRH is thought to stimulate thyrotrophs and promote their proliferation, which leads to pituitary hyperplasia. Therefore, TSBAb is assumed to factor into the failure to suppress TRH secretion and normalize pituitary size.

Pituitary hyperplasia due to primary hypothyroidism is known to be responsive to thyroid hormone replacement therapy [13]. In our case, the pituitary gland volume was reduced by approximately 50% after ten months of levothyroxine replacement therapy. However, the molecular mechanism by which pituitary gland volume shrinks with thyroid hormone replacement therapy is unknown. The pituitary gland volume in prolactin-producing adenomas is reportedly reduced by the administration of bromocriptine, a dopamine agonist [14]. Although past reports suggested the tumor-size-reducing effect of bromocriptine occurs through cellular necrosis with infarction [15–17], transmission electron microscopy revealed the molecular mechanism to be based on shrinkage of cell volume rather than a decrease in cell number due to cellular necrosis [18, 19]. Here, thyroid hormone replacement therapy may have caused the pituitary gland volume to regress as a result of volume shrinkage of thyrotrophs due to low stimulation of TRH followed by a decrease in the ability to produce TSH.
The pituitary volume did not converge to a normal size during the clinical course of about 16 years. This is thought to be mainly due to the patient’s non-adherence concerning levothyroxine intake, where frequent non-adherence provoked excessive TRH production through the loss of negative feedback in the hypothalamus-pituitary-thyroid axis, which led to pituitary hyperplasia. That is why the pituitary gland enlarged and contracted repeatedly. However, based on the fact that shrinkage of cell volume has been reported as the molecular mechanism of pituitary volume reduction [18, 19], the pituitary gland may not return to a normal size after the appearance of a profound pituitary hyperplasia.

In conclusion, we reported a case of long-term follow-up over 16 years for pathologically diagnosed pituitary hyperplasia due to primary hypothyroidism with positive thyroid stimulation blocking antibody. This report highlights the fact that the pituitary volume may not converge to a normal size after the appearance of profound pituitary hyperplasia. The patient’s non-adherence with levothyroxine intake caused a reversible pituitary enlargement, leading to symptoms due to compression of the optic chiasm and increased intracranial pressure. In the case of poor medication adherence, medication guidance is important to be provided assiduously for the prevention of profound pituitary hyperplasia, while using TSH and PRL levels as indicators.

**Abbreviations**

- TSH thyroid stimulating hormone
- TRH TSH-releasing hormone
- CT computed tomography
- MRI magnetic resonance imaging
- PRL prolactin
- FT3 free triiodothyronine
- FT4 free thyroxine
- ACTH adrenocorticotropic hormone
- LH luteinizing hormone
- FSH follicle stimulating hormone
- GH growth hormone
- TRAb thyrotropin receptor antibody
- TSBAb thyroid stimulation blocking antibody
TPOAb anti-thyroid peroxidase antibody
TgAb anti-thyroglobulin antibody
LHRH LH releasing hormone
