Abstract

Background Antimicrobial growth promoters (AGPs) are included in commercial animal feed rations in many low- and middle-income countries. We measured antimicrobial use (AMU) in commercial feed products consumed by 338 small-scale chicken flocks in the Mekong Delta of Vietnam, before a nationwide ban on AGPs which is to be phased in over the coming three years. We reviewed the labels of commercial feeds and calculated amounts of antimicrobial active ingredients (AAIs) given to flocks, highlighting those that did not comply with Government regulations.

Results Thirty-five of 99 different antimicrobial-containing feed products (35.3%) included at least one AAI. Eight different AAIs (avilamycin, bacitracin, chlortetracycline, colistin, enramycin, flavomycin, oxytetracycline, virginamycin) belonging to 5 classes were identified. Brooding feeds contained antimicrobials the most (51.2%), followed by grower (34.6%) and finisher feeds (12.5%). The average amount of AAIs given to flocks per kg of chicken at consumption time was 84.8 (SEM ± 9.3 mg). Quantitatively, chlortetracycline was consumed most (42.2 mg/kg SEM ± 0.34; 50.0% of total use), followed by enramycin (18.4 mg SEM ± 0.03, 21.8%) and bacitracin (16.4 mg SEM ± 0.20, 19.4%). Antimicrobials in commercial feeds were more commonly given to flocks in the earlier part of the production cycle. A total of 10 (9.3%) products were not compliant with existing Vietnamese regulation (06/2016/TT-BNNPTNT) either because they included a non-authorised AAI (4), had AAIs over the permitted limits (4), or both (2).

Conclusions and recommendation We found a discrepancy between current legislation and the types and quantities of AGPs found in chicken feeds; this may be a challenge in coming years when the full ban is implemented, and would require that the authorities step up monitoring efforts. Results from this study should encourage discussion about policies on AGPs in low- and middle-income countries.

Background

Antimicrobials are used in veterinary medicine for treating and preventing animal disease. In addition, in many countries antimicrobial growth promoters (AGPs) are added to commercial feed rations to promote growth and productivity (1).

The global annual consumption of antimicrobials intended for animal use has been estimated approximately 63 thousand tonnes. In European Union (EU) countries, all of which have well-developed antimicrobial use (AMU) surveillance systems, antimicrobials intended for animal use represent about 2/3 of total AMU (2). It is believed that excessive use of antimicrobials (including AGPs in feeds) in animal production is a major factor contributing to the global rise in AMR (3–5). The total amounts of antimicrobials intended for animal production are expected to increase in coming years due to intensification of livestock production, mostly in low- and middle-income countries (6).

Since AGPs were discovered more than 60 years ago, they have been used extensively in terrestrial animal production worldwide although their mechanism of action remain unknown (1). Only in recent
years, some countries have started to implement bans on AGPs or restrictions in their use. In the European Union AGPs have been banned since 2006 (7). In the USA, voluntary phasing out of certain AGPs has been implemented since 2013 (8). In the Asia-Pacific region, several countries have implemented a full ban of AGP in animal feeds in Korea (2011), Australia (2013) (9), Thailand (2015) (10); or restricting certain AGPs in China (2016) (11) and India (2019) (12).

Worldwide annual consumption of poultry meat (2013–2015) stands at 110,280 tonnes, second only to pork (117,005 tonnes). By 2025, chicken production is expected to surpass that of pork production(13). Until recently, AGPs have been extensively included in pig and poultry rations in Vietnam. Extrapolation from a retail survey estimated that in Vietnam 77 mg of AGPs are used to produce 1 kg of chicken (14). A study of medium-sized chicken farms estimated that chickens consumed 57 mg of AGPs per kg of chicken produced (15). However the study was based on a small sample of 6 farms.

A 2002 Vietnamese government regulation on animal feeds (54/2002/QĐ-BNN) included the ban of 18 chemicals (including chloramphenicol, metronidazole and nitrofurans) (16). Later (2014), new legislation (28/2014/TT-BNNPTNT) expanded this list to bacitracin, carboxax and olaquindox (17). In May 2016 Vietnam issued Circular 06/2016/TT-BNNPTNT (18) explicitly indicating the list of AAIs authorized to be used in commercial feed types as AGPs, as well as the maximum levels allowed in each feed type. According to this regulation, the maximum number of different AAIs to be included in each feed was limited to two. In 2018, Vietnam introduced an Animal Law (32/2018/QH14) (19) which included a ban on AGPs in commercial feeds. A further decree (13/2020/ND-CP) (20) established the timeframe for its implementation: critically-important AAIs still can be used until the end of 2020, highly important AAIs until the end of 2021, important AAIs until the end of 2022 and other permitted AAIs until the end of 2025.

This study aimed at investigating the types and quantities of AAIs in commercial feed in a large representative cohort of small-scale chicken flocks in the Mekong Delta region of Vietnam immediately before the implementation of the new Animal Law. This information complements existing data on antimicrobials administered by farmers (normally mixed in water) (21), providing a comprehensive picture on AMU in small-scale chicken flocks in the region. The situation of AGP in chicken farming is likely to be comparable to other countries in the region yet to implement a ban, as well as should form a baseline in order to confirm future reductions in AMU in animal production in Vietnam.

Results

Description of commercial feed products

A total of 99 different commercial feed products were identified. Those products were produced for usage in chicken (85 products, 85.9%), pig (12, 12.1%), and duck (2, 2.0%). Feed products were classified according to their indication (production stage): brooder (n = 40), grower (n = 24) and finisher (n = 35). A total of 35 (35.3%) contained at least one antimicrobial. All of the 35 antimicrobial-containing feeds were intended for chicken use. The detailed information on these antimicrobial-containing products is
available in Supplementary Table 1. Brooder feed products contained AAl's the most (51.2%), followed by grower (34.6%) and finisher (12.5%) feeds. All except one product (a brooder feed that contained both chlortetracycline and colistin) contained one AAI. A total of 12 (34%) products had an imprecise (ambiguous) label, indicating they contained one of 2–4 listed AAl's. A total of 8 different AAl's belonging to 5 classes were listed in the 35 feed products. The most common AAl's listed were enramycin (18.8% feeds), followed by bacitracin (16.5% chicken feeds), chlortetracycline (15.3%), avilamycin (5.9%), flavomycin (4.6%), colistin (3.7%), virginamycin (2.4%), and oxytetracycline (1.2%) (Table 1). A total of 10 (9.3%) products were not compliant with Regulation 06/2016/TT-BNNPTNT, either because they included a non-authorised AAl (avilamycin, flavomycin, oxytetracycline) (n = 4), AAl/s over the permitted limits (n = 4), or for both reasons (n = 2).

*Critically important antimicrobial class according to WHO. **AAl permitted in chicken feeds from 1 to 28 day old birds (brooder and grower feeds) (18). NA = Not allowed. † Antibiotic complex of obtained from Streptomyces bambergiensis and Streptomyces ghanaensis.

Flock consumption of AMUs through commercial feed
All flocks used commercial chicken feed. In addition, pig and duck feeds were given to 12.1% and 0.6% flocks, respectively. Each flock had been given a median of 2 [IQR 2–3] different commercial feed products. Flocks received a median of 1 [IQR 1–1] antimicrobial-containing products. Chickens were fed a mean of 84.8 (SEM ± 9.3 mg) [range 71.4–98.2] of AAI/kg over their production cycle. Chickens raised in Thap Muoi and Cao Lanh districts were given 87.7 (Standard Error of the mean, SEM ± 14.8 mg/kg) [range 76.1–99.3] and 81.7 (SEM ± 11.0 mg/kg) [range 66.3–97.1], respectively. Overall, the highest magnitude of AMU corresponded to chlortetracycline (42.2 mg SEM ± 0.34), followed by enramycin (18.4 mg SEM ± 0.03) and bacitracin (16.4 mg SEM ± 0.20) (Table 2).

NC = Not calculated. *Critically-important antimicrobial class according to the World Health Organization.

Commercial feed rations were given to flocks in at total of 5,655 of 6,041 (93.6%) observed weeks. The probability of AMU in flocks decreased with the age of the flock (Fig. 1a). On average, flocks were given AGPs in feed on 57.5% (95% CI 54.5–60.5%) weeks. Interestingly, a relatively high fraction of brooder products were used in later stages, while some finisher products were also used more in the growing
period. Enramycin was used dominantly throughout the production cycle, while colistin was found only in later stages (Fig. 1).

**Discussion**

There are very few published data describing and quantifying consumption of AAIs (AGPs) in commercial feeds in poultry farming systems in low-and middle income countries (LMICs) (6). Our findings complement existing data on antimicrobials administered to chicken flocks (mainly through water) (~792 mg/kg) in the Mekong Delta region of Vietnam (21). Consumption of in-feed antimicrobials over the life of the flock (~85 mg/kg), represents ~10% of total flock AMU. These figures are consistent with previous estimates (77–95 mg/kg) (14, 15).

This study is based on data from a large cohort study aiming at reducing AMU in chicken production in the Mekong Delta of Vietnam (22). The study is representative since the selection of farms was random. Even though our data came from an intervention study, our advice to farmers was focused on reducing AMU as medicine (both prophylaxis and therapeutic), and did not include any advice on feed. We did not find any difference between flocks allocated to the intervention compared with the baseline phase (data not shown).

A major concern is the relatively high number of products that did not comply with Vietnamese regulations. Bacitracin, banned in feed rations in Vietnam since May 2016 (18), was the second most common AAI found. More worryingly, 6/35 (17%) antimicrobial-containing feeds included AAIs in concentrations above those permitted by the Vietnamese authorities. For example, the colistin concentration in all feed products examined was 3–5 times greater than that permitted by the Government. Non-authorised antimicrobials (avilamycin, flavomycin, oxytetracycline) were also found in some chicken feeds. This raises concerns regarding compliance of commercial feed mills with regulations and casts doubts over the effective enforcement of the new decree on animal feeds (19, 20). An additional challenge is the ambiguous labelling with regards to AAI in about a third of the rations investigated, posing an additional difficulty to Government authorities for quality control.

Recent studies have reported a high prevalence of colistin resistance encoded by *mcr-1* in chicken flocks in the area (15, 23). This antimicrobial, classified as highly critically important by WHO (24), was listed in 5% feeds examined (brooder feeds) and it was estimated that on average, flocks consumed 5 mg/kg (about 3% of total in feed AMU). Compared with the reported magnitude of AMU through water administration (42 mg/kg) this is a modest amount. However it is of concern that in our study cohort farms tended to use these feeds towards the end of the production cycle with high drug concentration. This resulted in long elimination profile of antimicrobials, therefore high risk of residues in poultry meat (25).

Quantitatively, chlortetracycline, bacitracin and enramycin were the AAIs most consumed through commercial feeds. Tetracyclines were also the most consumed antimicrobial administered through water (21). Tetracyclines is also the class against which resistance among *Escherichia coli* and non-typhoidal
Salmonella strains in the Mekong Delta is highest (15, 23, 26–30). Bacitracin has been shown to promote resistance among Clostridium perfringens isolates from chickens (31–33). With regards to enramycin, there is little information on its impact on AMR. A Japanese study that investigated Enterococcus faecium isolates from chicken flocks found no evidence of resistance against enramycin (34), although the study presented no enramycin use data.

The inclusion of AGPs in animal feeds and its impact on human health have been the subject of heated debate since the ban of AGP in animal production in Europe (35, 36). A major concern in Europe was the widespread use of avoparcin (glycopeptide) as AGP in animal feeds, which resulted in vancomycin resistance among zoonotic Enterococcus faecium bacteria (37). In contrast, studies have indicated that the use of enramycin and bacitracin as AGPs involves no risk to human health (38, 39). The association between AGPs in animal feeds and human health beyond the scope of this study, and the evidence has been reviewed elsewhere (40). The finding that AAIs in feed were consumed during the latter weeks of the production cycle is of concern given the potential for generating residues in chicken meat. A recent survey showed that 8.4% of chicken meat samples in Vietnam contained antimicrobials residues, with tetracyclines being the most common residue detected (41).

Many researchers have postulated that the withdrawal of AGPs may result in an increase use of antimicrobials for prophylaxis (prevention) or metaphylaxis (mass treatment) (9). In our study, AGPs in chicken feeds represented a small (10%) fraction of total AMU and probably have comparatively little impact on disease given the types of antimicrobials included. In low-biosecurity systems, the economic impact and productivity of AGP have been proven to be higher than in optimized-biosecurity production units (9). However, a number of studies recently have been highlighted the overall poor effects of AGPs in poultry productivity (42, 43). In the Mekong Delta region of Vietnam, high incidence of infectious disease and losses due to mortality are thought to be the major drivers of productivity. In such cases the potential weight gains are unlikely to be noticeable.

**Conclusion**

Our results provide quantitative data on the magnitude of AMU through feed in chicken flocks in the Mekong Delta of Vietnam. It is of concern that a considerable number of feed formulations did not comply with Government regulations. Worryingly, all colistin-containing formulations had a concentration of AAI higher than that permitted by the current regulations. Results from this study should establish a framework for the quality assurance of antimicrobials used in commercial feed rations in Vietnam.

**Material And Methods**

**Farm selection**

Farm owners in two districts (Cao Lanh, Thap Muoi) within Dong Thap (Mekong Delta, Vietnam) were randomly selected from the official farm census and were contacted by the veterinary authorities.
Farmers about to start raising flocks of ≥ 100 meat chickens that practiced all-in-all out management were recruited, and flocks were followed up longitudinally. A total of 115 farms were recruited (59 in Cao Lanh; 66 in Thap Muoi). Selected farms were part of a longitudinal study aimed at reduce AMU in chicken production through the provision of veterinary advice (22). Owners of selected farms were requested to record in detail the types of commercial feed used and to keep the sacs of all feed products used. A field study team visited farms four times over the production cycle to collect data on commercial feed products used by week. A total of 338 flocks raised in these farms were investigated. Of the 115 farms, 44 completed 1 cycle (38.3.4%), 25 (21.7%) 2 cycles, 8 (7.0%) 3 cycles, 11 (9.6%) 4 cycles, 12 (10.4%) 5 cycles, and 15 (13.0%) more than 5 cycles. The median flock size at restocking was 303 [IQR 200–500]. A total of 6,041 weeks of data were collected. The median duration of one production cycle was 19 [IQR 17–21] weeks. All farm visits were conducted from October 2016 to Oct 2019.

AAIs in commercial feed products

All commercial feed products containing an antimicrobial active ingredient (AAI) were singled out after reviewing their label. Ionophores (mostly aimed at controlling coccidial infection) were excluded. AAIs were described by: (1) target species (duck, chicken or pig); (2) indication by stage of production (brooder, grower or finisher); and (3) type of formulation (crumbs, mash or pellets). From each feed product, we described the AAIs contained, its concentration (expressed in mg/kg product). AAIs were classified based on the OIE list of antimicrobial agents (44) and any antimicrobials regarded as critically important by WHO were highlighted (24). We excluded ionophores since it is thought that these substances, commonly used as coccidiostats, do not have any link with AMR or against antimicrobials commonly used to treat human or animal bacterial disease (45). We identified those feed products containing antimicrobials at concentrations not permitted under Vietnamese legislation (18).

Data analyses

We calculated AMU consumption in feed by week by relating the amounts of AAI (mg) to the weight of birds at the time of consumption (standard weight of the flock) (kg) (mg/kg live chicken) for all weeks (n) over the flock’s life duration (Expression 1).

\[
mg/kg \text{ chicken at time of consumption } = \sum_{k=1}^{n} \frac{AAI_{\text{used}(mg)\text{in week } k}}{\text{standard weight of the flock (kg) at week } k}
\]

Weekly consumption of AAIs in feed was calculated by multiplying the weekly feed consumption by the AAIs concentration indicated in that feed. The feed consumption was estimated from published data related to native Vietnamese layer pullets, where 443 g of feed were consumed by 1 kg of live chicken per week (46). The denominator (total weight of the flock at week k) was calculated from the number of chickens present in the flock multiplied by an estimated (standard) weight. The latter was based on weekly data from 10 randomly selected chickens from 11 representative flocks, from week 1 until week 22 of their production cycle (21).
The concentration (strength) of AAI in each feed product was obtained from its label. However information in a number of feed products contained uncertain information in their labels, concerning the identity of the AAI and the amounts included. For feed products with AAI content ambiguously labeled (i.e. indicating inclusion of one of > 1 listed AAI's), the amount of each AAI was calculated by assigning each antimicrobial a probability corresponding being included (probability = 1), and not being included (probability = 0). For products indicating their AAI's concentration as a range, lowest and highest estimates were calculated for each antimicrobial. The amounts of each AAI were summarized in each flock by AAI and by week. The total amounts of each AAI were aggregated to calculate total consumption by flock, including the estimation of a lower and upper limit from the above calculations.

Declarations

Ethical approval and consent to participate

This study was granted ethics approval by the Oxford Tropical Research Ethics Committee (OXTREC) (Ref. 5121/16) and by the local authorities (People's Committed of Dong Thap province). All participating farmers consented to the study.

Consent for publication

Not applicable.

Availability of supporting data

All data generated or analysed during this study are included in this published article and in its supplementary information file.

Competing interests

The authors declare no competing interests.

Funding

The current study was funded by the Wellcome Trust through an Intermediate Clinical Fellowship awarded to Dr. Juan J. Carrique-Mas (Grant Reference Number 110085/Z/15/Z).

Authors’ contributions
NVC, BVH and JCM conceived and designed the study. BTK, DHP and NVC carried out data collection; NVC, MC and JCM performed data analyses; BTK, BDT contributed to data entry, NVC, BDT, DHP, JCM and GT contributed to writing up and editing. All authors read and approved the final manuscript.
