Abstract

Individuals with religious or spiritual problem experience depressive and anxiety symptoms, together with changes in cognitive style and coping. These problems are associated with altered frontal asymmetry (left greater than right) during the processing of religious stimuli. The present study aimed to investigate the effect of pilgrimage on frontal asymmetry. Participants were 50 individuals experiencing religious or spiritual problem according to the DSM-5 criteria. Twenty-five of them participated in a two-week religious pilgrimage, and 25 matched volunteers went on non-religious holidays. We recorded resting-state EEG at baseline and after a religious phase (reading sacred text and listening to music) (NEUVO – CURRY 8X-system, 256-channel). The frontal asymmetry index was calculated for 1-min epochs by subtracting left electrode sites' logarithmically transformed alpha frequency from homologous right leads (F4-F3, F8-F7). Anxiety, depressive symptoms, and rumination were assessed with self-report scales. The psychological and EEG assessments were performed before and after the pilgrimage or holiday. Results revealed that individuals experienced less anxiety, depression, and rumination following the pilgrimage. There was a significant reduction of frontal asymmetry during the processing of religious stimuli in pilgrims. We found no similar changes in volunteers who went on a non-religious holiday. These results indicate that frontal asymmetry and negative emotionality are ameliorated during a pilgrimage in individuals with religious or spiritual problem.

Introduction

Recent decades have witnessed a radical shift in the clinical understanding of religious and spiritual experiences. Since the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV, 1994), Religious or Spiritual Problem (RSP) constitutes a separate phenomenon in a section focusing on issues related to psychosocial, personal, and environmental circumstances [1, 2]. Although RSP is not a mental disorder, it is often the focus of clinical attention. Individuals with RSP often experience marked anxiety and depressive symptoms related to doubts in faith, strains associated with conversion to a new faith, or questioning spirituality outside organized religious institutions [3]. Religion and spirituality are two related but distinct concepts that pertain to matters of belief, faith, and personal connection to the divine and transcendent. Religion is based on an organized belief system, rituals, authoritative sacred texts, dogma, doctrine, and group identity. In contrast, spirituality refers to the personal connection with the divine, universe, or a higher power with the dominance of inner experiences. It is less institutionalized and open to syncretism [4].

Recently, we investigated physiological stress responses in RSP during social-evaluative stress (public speaking) and in a religious context (Bible reading and listening to sacred music) [5]. We found elevated stress responses only in the religious context in RSP, as indicated by increased heart rate, saliva cortisol, and relatively higher left than right frontal activity. Frontal asymmetry is especially intriguing, indicating a cognitive style associated with RSP. A marked left frontal brain activity following a stressful situation may indicate an overload of cognitive coping mechanisms [6] linked to endocrine stress responses (increased cortisol secretion) [7]. Enhanced left relative to right frontal activity is an electrophysiological
marker of goal-oriented coping strategies, uncertainty in decision-making, repetitive and perseverative thoughts, and rumination to resolve stressful situation effortfully [7–9].

There are several possible solutions to RSP. Many people embark on a pilgrimage to process their thoughts about the crisis, get out of the daily routine and find peer support. We investigated how frontal asymmetry changes during the pilgrimage relative to non-religious holidays, together with depressive and anxiety symptoms. We hypothesize that left relative to right frontal activity decreases after the pilgrimage, with reduced anxiety and depressive symptoms. We also hypothesized that reduced left vs. right frontal asymmetry is related explicitly to rumination.

**Methods**

**Participants and general procedure**

The study included 50 individuals with RSP from Hungarian religious communities (34 Roman Catholic, 16 Protestant) who defined themselves as highly religious believers according to the survey of the Hungarian Central Statistical Office (Budapest, Hungary). First, volunteers received the structured interviews and rating scales and then participated in EEG measurements in a neutral-everyday and religious context. The procedure was performed two times: before and after two weeks, during which 25 individuals (21 Roman Catholic, 4 Protestant) participated in a religious pilgrimage (Máriaradna pilgrimage, and Mátraverebély-szentkút Franciscan friary, Christian pilgrimage routes in Hungary and Romania, Transylvania area) and 25 participants (22 Roman Catholic, 3 Protestant) went on a non-religious holiday (hiking and sightseeing in Hungarian and Romanian destinations). The participants aimed to reduce stress and strain in their life during the pilgrimage or holiday. The two groups did not differ in confounding factors affecting stress responses, including smoking, alcohol intake, exercising before participation, hours of sleep in the previous night, being postmenopausal, acute or chronic illness, hormonal contraception, and distance walked during the pilgrimage and holiday) [10, 11] (Table 1).

The study was conducted in accordance with the Declaration of Helsinki and approved by the United Ethical Review Committee for Research in Psychology (EPKEB, 2016/032) at the Budapest University of Technology and Economics and the National Medical Research Council (ETT-TUKEB 18814, Budapest, Hungary).

**Interviews and questionnaires**

We applied the clinical interview for DSM-5 (Diagnosis and Statistical Manual of Mental Disorders – 5) [12]. All participants meet the DSM-5 definition of "Problems related to other psychosocial, personal, and environmental circumstances" (Religious or Spiritual Problem, code: V62.89) [3]. We used the Beck Depression Inventory-II (BDI-II) and the Beck Anxiety Inventory (BAI) [13] to characterize negative emotional responses associated with RSP. Rumination (brooding and reflection) was assessed with the Hungarian version of the 10-item Ruminative Response Scale [14]. We assessed intrinsic and extrinsic religiosity with the Age Universal I-E scale-12 [15, 16] (Table 1).
EEG measurements

The experiment was conducted between 11h and 17h. In the neutral phase (30-min), the participants relaxed in a quiet room, reading newspapers and listening to non-religious music. At the end of this phase, we conducted the EEG measurements. Immediately after the neutral phase, the volunteers participated in the religious phase (30-min): they read verses from the Bible and listened to sacred piano music [5]. Following the religious phase, the EEG measurements were repeated.

We recorded resting-state EEG at baseline and after the religious phase, as described previously [5]. "EEG was recorded and processed with a NEUVO – CURRY 8X-system with a 256-channel Quik-Cap Neo Net (high-density EEG cap, Ag/AgCl electrodes, four bipolar leads for vertical and horizontal electrooculogram, extended international 10–20 system) (Compumedics, NeuroScan). The electrode impedances were checked (< 5 kΩ, homologous bilateral leads: < 1 kΩ). The sampling rate was 500 Hz. For data processing, we used the EEGLAB interactive MATLAB toolbox (Schwartz Center for Computational Neuroscience, University of California). Each measurement included eight 1-min resting periods (four occasions with eyes open and four with eyes closed, counterbalanced across subjects). Following built-in automatic and manual artifact reduction, the 1-min epochs were segmented in 2-s periods with 75% overlap between epochs (epoch amplitudes < ±75 µV) and were low-pass filtered at 30 Hz [7]. We used Fourier transformation to generate the spectral power (µV²) (resolution of 0.488 Hz) in the alpha band (8–13 Hz). Every 1-minute EEG registration included at least 20 2-s epochs, and power density was averaged using all epochs. We used logarithmic transformation (ln) for averaged power density values. We calculated the frontal asymmetry index for the 1-min epochs by subtracting the logarithmically transformed alpha frequency of left electrode sites from homologous right leads (e.g., F4-F3, F8-F7). Higher alpha-asymmetry scores indicate relatively more robust left-sided frontal activation [7, 17]."

Data analysis

We used STATISTICA 13.5 (Tibco) for data analysis. The data were checked for normal distribution (Kolmogorov-Smirnov test) and homogeneity of variance (Levene's test). Data were entered into repeated measures analyses of variance (ANOVAs). Tukey's HSD (Honestly Significant Differences) tests were applied for post hoc analysis. The demographic and rating scale scores were analyzed with two-tailed t-tests and chi-square tests (sex distribution). The level of statistical significance was set at alpha < 0.05. Effect sizes (r²) were also calculated for ANOVA main effects and interactions, and 95% confidence intervals were reported.

Results

Demographics and rating scales

Individuals with RSP who participated in a pilgrimage and a non-religious holiday did not differ in age, education, religiosity, and sex distribution (ps > 0.5). Before the pilgrimage or holiday, the two groups
scored similarly on the BDI-II, BAI, and RSS-10 scales ($p$s > 0.2). However, after the pilgrimage or holiday, we observed significantly lower BDI-II scores ($t(48) = -4.82, p < 0.001$), BAI scores ($t(48) = -4.44, p < 0.001$), and RSS-10 scores ($t(48) = -3.69, p < 0.005$) in the pilgrim group relative to the non-religious holiday group (Table 1).

Frontal asymmetry

Regarding the left vs. right frontal activity, there were no significant main effects of group (individuals with RSP participating in a pilgrimage and non-religious holiday) ($p = 0.82$) and testing session (before and after pilgrimage or non-religious holiday) ($p = 0.98$). However, the main effect of session type (neutral and religious) was significant ($F(1,48) = 304.66, p < 0.001, \eta^2 = 0.86$), with significantly higher frontal asymmetry in the religious condition than in the baseline condition ($p < 0.001$) (Fig. 1). The two-way interactions between group and testing session ($p = 0.05$), and group and session type ($p = 0.34$) were not significant. Critically, the three-way interaction among the group, testing session, and session type reached the level of significance ($F(1,48) = 9.94, p < 0.01, \eta^2 = 0.17$). Tukey's HSD tests indicated that the frontal asymmetry in the religious condition significantly decreased in pilgrims ($p < 0.05$) but not in those who went on a non-religious holiday ($p = 0.47$). In the neutral phase, we found no significant differences in either condition ($p$s > 0.5) (Fig. 1). We found no significant correlations between frontal asymmetry and rating scale scores (BDI-II, BAI, and RRS-10) ($p$s > 0.2).

Discussion
We found support for our central hypothesis: individuals with RSP showed reduced left vs. right frontal activation when exposed to sacred text and music following the pilgrimage. They also experienced less anxiety and depressive symptoms. However, we did not find associations between frontal asymmetry and rumination. Interestingly, individuals with RSP who participated in a non-religious holiday did not exhibit significant changes in frontal asymmetry and negative emotional experiences.

The DSM concept of RSP has precedents and parallels in the literature. Extensive research dealt with the issue of religious and spiritual struggle [18–20]. Two major components of RSP in the DSM, the "loss or questioning of faith" and "conversion to a new faith," are similar to divine struggles (anger or disappointment with God) and doubt-related struggles (confusion and doubt about religious/spiritual beliefs and values) [20]. The "questioning of spiritual values" in the DSM resembles moral struggles (guilt about not living according to the standards of the religion) and struggles of ultimate meaning (concerns related to the deeper value and meaning of life) [20]. However, a high covariance exists between the separate dimensions of religious and spiritual struggle (divine, demonic, doubt-related, moral, ultimate meaning, and interpersonal), revealing a general RSP factor [21].

Numerous attempts have been made to treat religious or spiritual problems with psychotherapies [18, 22, 23]. The present study has shown that pilgrimage can productively alleviate negative emotions associated with religious and spiritual crises and changes in frontal asymmetry. Following the religious journey, the pilgrims did not report religious or spiritual problem and exhibited markedly reduced anxiety and depressive symptoms. We observed no similar changes in individuals participating in secular traveling and relaxing activities. However, the present study did not fully answer how frontal asymmetry is related to subjective negative experiences. Contrary to our hypothesis, we found no relationship between frontal asymmetry and rumination. Therefore, further studies are warranted to unravel the cognitive correlates of altered frontal asymmetry in combination with other constituents of the stress response.

At baseline, the pilgrim and the holiday groups did not differ in age, sex, education, anxiety, depression, religiosity, and EEG measures, which supports their comparability. However, individuals participating in a pilgrimage and a non-religious holiday were not randomized, and therefore a hidden group-related bias cannot be excluded. Another limitation is that we could not conclude the effect on different religious denominations because of the small sample size (Roman Catholic vs. Protestants), and we did not assess the durability of the pilgrimage's effects over time. The final limitation is that we did not use a rating scale for religious and spiritual struggle; only the DSM-5 criteria were applied. It is essential to underline that the pilgrimage phenomenon is not monolithic, as it contains diverse sociocultural dimensions that can influence the outcome. The present study was conducted in an Eastern-European Christian context, mainly Roman Catholic.

In conclusion, when religious stimuli are processed, religious or spiritual problems are characterized by left vs. right frontal asymmetry. This frontal asymmetry is ameliorated after the pilgrimage. Further studies are needed to elucidate the relationship between frontal asymmetry and religious cognitions and their changes following interventions in psychological and spiritual crises.
Declarations

**Institutional Review Board Statement:** The study was conducted in accordance with the Declaration of Helsinki and approved by the United Ethical Review Committee for Research in Psychology (EPKEB, 2016/032) at the Budapest University of Technology and Economics and the National Medical Research Council (ETT-TUKEB 18814, Budapest, Hungary). Written informed consent has been obtained from the participants.

**Acknowledgments:** I thank Ibolya Halász, Katalin Kaza, and Péter Nagy for their assistance.

**Conflicts of Interest:** The author declares no conflict of interest.
