Abstract

Background To analyze the differences in clinical features and computed tomography characteristics in the two types of mixed epithelial and stromal tumor of the kidney (MESTK) and to establish a treatment plan for the MESTK types.

Methods 17 patients underwent multidetector computed tomography (MDCT) before surgery and had a pathological diagnosis of MESTK were enrolled. Their clinical information (R.E.N.A.L.Nephrometry Score (R.E.N.A.L.ÑNS), radical nephrectomy (RN), partial nephrectomy (PN), etc.) were collected. The radiological features included renal sinus fat invagination (SFI), maximal diameter (MD), capsule and septa of the tumor, etc. were also analyzed. They were divided into two types according to the MD_{solid}/MD_{tumor} ratio (type A with $> 63\%$; type B with $\leq 63\%$). An independent-sample t-test and Fisher exact test were used to assess the differences between the two groups.

Results MESTKs demonstrated a variable multi-septate cystic and solid components with a delayed enhancement. There were 9 patients for type A and 8 subjects for type B. Compared with type A, the lesions in type B have larger MD (79.13 ± 39.06 vs. 41.22 ± 24.19 , $p = 0.028$), higher R.E.N.A.L.ÑNS (10.03 ± 0.50 vs. 8.95 ± 1.26 , $P=0.001$), higher RN (75.00% vs. 22.22%, $p = 0.015$), larger SFI (87.5% vs. 33.3%, $p=0.05$), more septa (100% vs. 0%, $p < 0.001$) and more capsule (100% vs. 11.1%, $p < 0.001$).

Conclusion Type B MESTK has more hazardous features compared with type A, suggesting that RN is more suitable for type B and PN for type A.

Main Text

Mixed epithelial and stromal tumor of the kidney (MESTK), first identified by Michal and Syrucek in 1998 (1), is a rare benign entity with a prevalence of 0.2% to 1.6% of all renal tumors (2, 3). Histopathologically, MESTK is composed of epithelial and stromal components (4). It appears as a cystic renal mass with varying proportions of solid components on imaging. The WHO grouped the lesion into the mixed epithelial and stromal tumor family in 2016 (5).

Surgical excision (partial nephrectomy (PN) and radical nephrectomy (RN)) is the most common treatment for patients with MESTK. PN should be recommended to preserve the nephron as much as possible in most MESTK patients because it is a benign entity. Therefore, an accurate evaluation of MESTK is vital for preoperative treatment planning. Previous studies have demonstrated the role of computed tomography (CT) and other imaging modalities including magnetic resonance imaging (MRI) and ultrasonography in evaluating the characteristics of the tumor (6-8). To the best of our knowledge, the largest radiological study on MESTK described the imaging features in eight patients (9). The classic imaging appearance of MESTK is that of a well-circumscribed, multi-septate cystic and solid mass with delayed enhancement (10-12).

In clinical work, the preoperative radiologic diagnosis of MEST is challenging and is easy to be misdiagnosed as other renal neoplasms – renal cell carcinoma (RCC) – leading to inappropriate treatment. Furthermore, it is still unclear whether the imaging features and clinical data can help make a suitable treatment plan for the patients with MESTK.

In our study, the patients with MESTK were divided into two types based on the proportion of MD_{solid} / MD_{tumor} in the maximal slice (type A: the ratio $> 63\%$; type B: the percentage $\leq 63\%$). Our purpose is to analyze the clinical and radiologic features of MESTK, with emphasis on evaluating the differences in clinical and computed tomography characteristics and proposing a patient management plan for the two types.

Material And Methods

Patients

Ethical approval was obtained from Institutional Review Board of the Xiangya Hospital, Central South University. This retrospective study was performed in accordance with the provisions of the Declaration of Helsinki. The requirement for informed consent was exempted by the Institutional Review Board of the Xiangya Hospital, Central South University as all data

was analyzed anonymously (number 2018111101). From June 2011 to November 2020, 17 patients pathologically diagnosed with MESTK (13 women and 4 men—the median age was 45.12 ± 10.77 years (range from 21 to 61y), who underwent preoperative multidetector CT (MDCT) within 15 days before the surgical procedure were recruited. The clinical information (the follow-up time, gender, age, clinical symptoms, menstrual status, surgery methods (PN and RN), and R.E.N.A.L. Nephrometry Score (R.E.N.A.L.-NS)) were collected (R= Radius (tumor size as maximal diameter); E = Exophytic/endophytic properties of the tumor; N = Nearness of tumor deepest portion to the collecting system or sinus; A = Anterior (a)/posterior(p) descriptor; and L= Location relative to the polar line(13)). For R.E.N.A.L.-NS, the range of 4 to 6, 7 to 9 and 10 to 12 were deemed low, moderate and high complexity lesions, respectively. The beginning and end of the follow-up period was the time the patient had surgery and the latest MDCT or ultrasound examination in our hospital.

MDCT techniques

All patients carried out plain and contrast enhancement MDCT scan in our hospital (128 slices, Somatom Definition, Siemens Healthineers, Erlangen, Germany; 320-slice, Toshiba Aquilion ONE, Canon Medical Systems, Otawara, Tochigi, Japan). The scanning parameters were as follows: slice thickness of 1mm, slice gap of 0mm, the pitch of 1.2, 100kVp and 200 mA for Somatom Definition and Aquilion ONE. For enhanced MDCT, a non-ionic iodinated contrast agent (iopromide, Ultravist; Schering AG, Berlin, Germany) was used at a rate of 3.5-4ml/s (1.5mL/kg, 80-100ml). The corticomedullary phase (CMP) (30s), the nephrographic phase (NP) (70s), and the excretion phase (EP) (3- 5 min) were obtained for each subject after injection of the contrast agent.

Imaging analysis

All MDCT images were transferred into the imaging workstation (Advantage

Workstation 4.4, GE Healthcare, Buc, France) and image post-processing (sagittal and coronal images) was performed. Two experienced radiologists (J.C. and G.P, reviewers 1 and 2 with 5 and 7 years of clinical experience in kidney MDCT, respectively) assessed the imaging characteristics without knowing the clinical and pathological information—including the maximal diameter (MD), shape, location, calcification, septa state, mural nodule, capsule of the tumor, renal sinus fat invagination (SFI), and the enhancement degree and pattern. SFI is defined as the direct contact of the tumor with the renal sinus stroma or fat cell (14), which appears as an invasion of the fat tissue of the renal sinus on MDCT. But it is not considered invasive if the tumor impinges on (but is separated from the fat by a connective tissue layer) the perinephric or renal sinus fat (15). Enhancement patterns were evaluated and analyzed with the CT attenuation for each phase for all MESTK. A region of interest (ROI) was drawn on the solid component of the tumor (size: 40- 60 mm²) on EP images, avoiding the cystic and calcified parts in the tumor. Then, it was copied to plain, CMP, and NP images of the same slice. For each subject, the above measurements were carried out two more times on different occasions within a week, and the average CT attenuation was calculated for each phase to obtain the enhancement pattern (wash out or delayed enhancement). Gradual enhancement pattern was considered present when the tumor attenuation in the nephrographic phase was at least 20 HU greater than that in the corticomedullary phase (16), while gradual washout pattern was defined when the CT value of the subsequent phase was reduced to less than 20 Hounsfield units (HU) (17). The degree of enhancement was defined as the difference between the attenuation value of the unenhanced scan and the CMP. A difference higher than 50 HU was classified as marked, between 20 and 50 HU as moderate, and less than 20HU as weak enhancement (6).

A threshold value of 25% (proportion of solid components in a cyst-solid tumor) is used in the Bosniak classification (version 2019) of renal cystic masses with solid components (18, 19). The Bosniak classification can be used for patients with cyst-solid mass when the proportion of solid part $\leq 25\%$. But, the Bosniak classification cannot be applied when the percentage of the solid element $> 25\%$. However, it is difficult for radiologists to estimate - qualitatively - the volume percentage of the solid part on MDCT. The volume of mass and solid components are relative to their respective diameter (D) ($V = (4/3)\pi R^3$ and $R = D/2$), So, the maximal diameters (MD) were used to replace the corresponding volume in our study, and the equation is as follow:

$$\text{Ratio} = \text{MD}_{\text{solid}} / \text{MD}_{\text{tumor}} \quad (1)$$

where MD_{tumor} is the maximal diameter of tumor in the slice in which the mass has the greatest size and MD_{solid} is the maximal diameter of the solid part in the same slice. When the ratio of the MD of the solid part in mass $\leq 63\%$, it was classified into type B (can be classified with Bosniak classification), and into type A when the ratio $> 63\%$ (cannot be classified with Bosniak classification). The detailed illustration is shown in Fig.1.

For lesions classified into type B, the number of septa, septal thickness, septal enhancement, wall thickness, wall enhancement, and mural nodularity on MDCT were assessed, and Table 1 gives the reference standard during image analysis. Lesions were classified into I-IV category with Bosniak Classification(18).

Statistical analysis

An independent-sample t-test was used to assess differences in the MD, age, and R.E.N.A.L.ÑNS between type A and type B. The Fisher exact test was used to analyze gender, clinical symptoms, surgery methods, shape, RSI, calcification, septa, mural nodules, capsules, and enhancement patterns in the two groups. Statistical analyses were performed with SPSS 18.0 (SPSS Inc., Chicago, IL, USA). P-value > 0.05 was considered not statistically significant

Results

Clinical findings

In the 17 patients, MESTK was detected incidentally in the majority of the patients without any symptoms ($n=10$, 58.82%); five patients presented with flank pain, and 2 patients presented with hematuria. MESTK occurred mainly in female ($n=13$, 76.5%) compared to men ($n=4$, 23.5%), with a predilection for perimenopausal women ($n=9$, 69.23%). For R.E.N.A.L.ÑNS, the score ranged between 7-11 with a mean score of 9.35 ± 1.17 (low: $n=0$; moderate: $n=7$ (41.18%); high: $n=10$ (58.82%)) in our study. Two cases (11.76%) showed solid components extending into the renal pelvis and ureter (Cases No. 3 and 16; Fig. 2), and both of their R.E.N.A.L.ÑNS were 10. All subjects underwent surgery (PN: $n=8$ (47.06%); RN: $n=9$ (52.94%)), and the longest follow-up time was 114 months. No metastasis or recurrence was found in the patients after surgery and the renal function remained normal during the follow-up period (An additional movie file shows this in more detail [see Additional file 1]). The clinical details are shown in Table 2.

Imaging findings

All MESTKs demonstrated a variable proportion of multi-septate cystic and solid components, which appeared as delayed enhancement with a well-circumscribed margin on triphasic dynamic-enhanced MDCT (Fig 3, 4), except for two subjects that had gradual washout pattern. The CT attenuation was less than 20 HU in the cystic part. In the 17 cases, the tumor in 14 patients (77.8%) showed a regular shape, and 10 subjects (58.82%) demonstrated RSI (Fig 5A). In addition, tumor capsule was present in 7 patients (41.1%) (Fig 5B), and regular or irregular septa was present in 4 patients (22.2%) (Fig 5C). The MDCT findings are shown in Table 3.

The comparison of type A with type B

In our study, 9 patients with MESTK were classified into type A (Fig 3) and 8 subjects into type B (Fig 4). Based on the Bosniak classification, the lesions in the type B group were classified as category 0 ($n=0$), 1 ($n=1$), 2F ($n=0$), 2 ($n=3$), and 3 ($n=4$). Compared with type A, the lesions in type B have larger MD (79.13 ± 39.06 vs. 41.22 ± 24.19 , $p=0.028$), higher R.E.N.A.L.ÑNS (10.03 ± 0.50 vs. 8.95 ± 1.26 , $P=0.001$), higher RN (75.00% vs. 22.22%, $p=0.015$), greater SFI (87.5% vs. 33.3%, $p=0.05$), septa (100% vs. 0%, $p<0.001$) and more capsule (100% vs. 11.1%, $p<0.001$). Besides, there was no significant difference between the type A and B groups regarding age, gender, clinical symptoms, the shape of the tumor, location of the tumor, calcification, mural nodule, and enhancement pattern (all p values > 0.05) (Table 4).

Discussion

As a member of the mixed epithelial and stromal tumor family, the imaging characteristics of MESTK and its connection with patients' management remain largely unknown (5). Most of the current literature on MESTK focused on its pathologic features (20, 21), with only a small number of case reports and case series addressing its radiologic features (11, 22). In our study, 17 patients with MESTK who had an MDCT were collected-the largest imaging series to the best of our knowledge-to analyze the imaging and clinical features and with emphasis on providing a reference for patients' management based on the difference in the two types of MESTK.

The typical clinical symptomatology of MESTK includes flank pain, hematuria, or symptoms related to genitourinary infections (20). In our research, only five patients with flank pain and 2 subjects with hematuria were found in the 17 MESTK cases. However, most of them (10 patients, 58.82%) were detected MESTK incidentally without any symptoms, which was consistent with the findings of Lane et al. (9). The possible reason may be advances in imaging modalities and the prevalence of health examinations. Also, MESTKs were found in 13 females (76.5%): 9 of whom were perimenopausal (69.23%). This suggests that perimenopausal females had the predominance of MESTK due to the serum estrogen level. The findings are in accordance with previous studies (20, 23, 24).

R.E.N.A.L.-NS is a crucial scoring system for patients with renal masses, promoting a standardized communication and standardization of clinical care patterns [13]. Renal tumors with low to moderate complexity (R.E.N.A.L.-NS ≤ 9 scores) are often treated with PN, whereas RN is done for high complex lesions (R.E.N.A.L.-NS > 9 scores) (25). In our study, the range of R.E.N.A.L.-NS was 7–11 score and the mean score was 9.35 ± 1.17 score (low: $n = 0$; moderate: $n = 7$ (41.18%); high: $n = 10$ (58.82%)). 7 patients (R.E.N.A.L.-NS ≤ 9 score) underwent PN and 9 patients (R.E.N.A.L.-NS ≥ 9 score) had RN. Only one patient (case 16, R.E.N.A.L.-NS = 10 score) chose PN due to the patient's strong desire to preserve the kidney and because the tumor was located mainly in the pelvis and ureter. Also, there were no signs of recurrence or metastasis for all patients during the follow-up time, although the metastasis of MESTK has been reported (26). It indicated that the choice of treatment is successful for all persons.

MESTKs are unilateral and single lesions with different proportions of solid components (8, 11, 12, 16). Our cases demonstrated well-circumscribed expansile lesions with a variable proportion of multi-septate cystic and solid components, having delayed enhancement on triphasic dynamic-enhanced MDCT. The delayed enhancement may be related to the abundance of collagen fibers, which restrict the diffusion of contrast agent within the tumor (4, 17). Lane et al. found that MESTK commonly tends to extend into the renal sinus (9). In our study, 10 subjects (55.5%) have demonstrated SFI, indicating that nephron-sparing surgery is not the best management plan for such tumors compared to those without the SFI.

In our study, Type A in MESTK is composed mainly of solid elements ($> 63\%$ for the ratio of the solid components' MD in the mass), while Type B consists principally of the cystic part ($\leq 63\%$ for the percentage of the solid element' MD in the tumor). Interestingly, the MD of tumor in type B was greater than Type A. The reason may be that epithelial elements existed more in type B than type A. These epithelia then secrete fluid that accumulates in many various cysts due to the epithelial cells containing much spatulate papillary architectures and tiny crowded glands (4). In addition, our findings showed that R.E.N.A.L.-NS in type B was higher than type A (10.03 ± 0.50 vs. 8.95 ± 1.26 , $P = 0.001$), which implies that patients in type B had a higher risk for urine leakage when PN is performed (27). Fortunately, the patients with type B underwent RN and therefore had no urine leakage.

SFI is not currently used in either the Robson or TNM staging systems. However, it is an important prognostic finding and staging parameter (14). Roberto et al. deemed that SFI significantly influenced disease-free survival and cancer-specific survival in patients without nodal or distant metastases (15). Stephen et al. suggested that RN should be recommended for those patients with renal sinus invasion (14). It is in line with our findings that 7 out of 8 patients (type B) with SFI had RN. Furthermore, type B had more septa than type A and met the Bosniak classification requirement, but type A did not satisfy it. Thus, MESTK Type B in our study presents as a multiloculated lesion with regular or irregular septa, which is different from type A (28). In addition, type B lesions have more capsules, caused by compression of adjacent renal tissue by the tumors correlating with the larger size of these tumors (29, 30).

Limitations of this study are the small number of MESTK cases, retrospective design, and single-center study. With advances in imaging modalities and the rising popularity of health examination, diagnosis of asymptomatic and small MESTK will increase

and promote a better treatment plan for patients' management.

Conclusion

In general, MESTK presents as a well-circumscribed lesion with a variable proportion of multi-septate cystic and solid components, showing a delayed enhancement on triphasic dynamic-enhanced MDCT. With a comparison of type A, type B MESTK has more hazardous features, such as larger MD, higher R.E.N.A.L.-NS, more RN, greater SFI, multiple septa, which suggests that RN is more suitable for type B lesions. Nephron-sparing surgery should be considered for type A cases.

Declarations

Ethics approval and consent to participate

Ethical approval was obtained from Institutional Review Board of the Xiangya Hospital, Central South University. This retrospective study was performed in accordance with the provisions of the Declaration of Helsinki. The requirement for informed consent was exempted by the Institutional Review Board of the Xiangya Hospital, Central South University as all data was analyzed anonymously (number 2018111101).

Cystic masses with thin (≤ 2 mm) and few (1-3) septa; septa and wall may enhance; may have calcification of any type* 2. Homogeneous hyperattenuating (≥ 70 HU) masses at unenhanced MDCT 3. Homogeneous non-enhancing masses ≥ 20 HU at renal mass protocol MDCT, may have calcification of any type# 4. Homogeneous masses -9 to 20 HU at unenhanced MDCT 5. Homogeneous masses 21 to 30 HU at portal venous phase MDCT 6. Homogeneous low-attenuation masses that are too small to characterize
⊠F	<p>Three types, cystic masses with enhancing wall or enhancing septa:</p> <ol style="list-style-type: none"> 1. Cystic masses with a smooth minimally thickened (3mm) enhancing wall 2. Cystic masses smooth minimal thickening (3mm) of one or more enhancing septa 3. Cystic masses with many (≥ 4) smooth thin (≤ 2 mm) enhancing septa
□	One or more enhancing thick (≥ 4 mm width) or enhancing irregular (displaying ≤ 3 -mm obtusely margined convex protrusion[s]) walls or septa
□	One or more enhancing nodule(s) (≥ 4 -mm convex protrusion with obtuse margins, or a convex protrusion of any size that has acute margins)
*Renal masses have abundant thick or nodular calcifications on MDCT; #Renal tumors are hyperattenuating, homogeneous, nonenhancing, and larger than 3cm on MDCT.

Figures

Figure 1

An example of lesion classification into type A and type B based on the proportion of solid components. In the Fig.1A (case 6), the maximum diameter of the mass (solid line) is 21.1mm, and the longest diameter of the solid component (dotted line) is 14.8mm in the same slice. Thus, the ratio is 70.1% $\frac{14.8}{21.1}$ according to the equation (Ratio = MDsolid / MDtumor), which is more than 63% and classified into Type A. In Fig.1B (case 5), the maximum diameter of the mass (solid line) is 75 mm, and the longest diameter of the solid part (dotted line) is 18.4mm. Thus, the ratio is 24.5% $\frac{18.4}{75}$ and classified into Type B (the ratio < 50%) on the basis of the equation (Ratio = MDsolid / MDtumor).

Figure 2

A 56-year-old woman with confirmed MESTK by pathological examination of surgical specimen (Case 3). Axial (Fig 2A) and coronal (Fig 2B, 2C) MDCT images in the excretory phase. The images show the solid-predominant mass extending into the pelvis and ureter (white arrow), which was confirmed histologically, Fig 2D (histopathological staining: consisted of the epithelium and stroma in the microscopy), Fig 2E (Immunohistochemical staining: positive for Estrogen receptors, represents the stromal element) and Fig 2F (Immunohistochemical staining: progesterone receptor-positive, illustrates the stromal cells).

Figure 3

A 52-year-old woman with flank pain (Case 13). A slightly hyperdense solid mass in the left kidney was found on the axial unenhanced MDCT (Fig 3A), which shows no enhancement on the corticomedullary phase (Fig 3B), slight enhancement on the nephrographic phase (Fig 3C), further enhancement on the excretion phase (Fig 3D). It was confirmed as MESTK by histopathological staining with the epithelium and stroma (Fig 3E) and immunohistochemical staining (Fig 3F: positive for smooth muscle actin, representing the stromal area; Fig 3G: positive for pan-cytokeratin, representing epithelial areas). The lesion (Case 13) was classified into type A according to the equation.

Figure 4

A 49-year-old woman with flank pain (Case 15), A cystic-solid mass is shown on an axial enhancement MDCT (Fig 4A), which displayed slight enhancement with multi-septate cystic and solid components on the corticomedullary phase (Fig 4B), prolonged enhancement on the nephrographic phase (Fig 4C) and the excretory phase (Fig 4D), and was confirmed as MESTK by histopathological (Fig 4E) and immunohistochemical (Fig 4F: the positive for pan-cytokeratin in the epithelium; Fig 4G: positive for vimentin in the stromal area). The patient (Case 15) was classified into type B (IV category). Compared with Fig 3 (Case 13), it has a variable proportion of cystic and solid components.

Figure 5

Some vital imaging features on MDCT. Renal sinus fat invagination (SFI) (white arrow) is shown on the sagittal MDCT (Fig 5A, case 7), which represents the tumor invasion into the sinus fat (white arrow). In addition, the capsule of the tumor (white triangle) is shown on a coronal MDCT (Fig 5B, case 12), and the multiple regular septa (white arrow) is shown in the tumor in the coronal MDCT (Fig 5C, case 11).
