Abstract

Identification of genes for tolerance against phosphorus (P) deficiency is important for wheat production in P-deficient soils. Nine root system architecture (RSA) and root biomass-related traits (RBT) in 198 double haploid lines derived from cross between Yangmai 16/Zhongmai 895 were characterized under zero (control), low, and high P treatments (KH_2PO_4 contents: 0, 0.005, 0.25 mmol/L, respectively) in hydroponic culture, and the DH lines and parents were genotyped using Wheat 660K SNP array. All traits showed significant variations among the DH lines with high heritabilities (0.76 to 0.91) and high correlations ($r = 0.59$ to 0.98) with each other. Inclusive composite interval mapping using 10,242 markers identified 34 QTLs for all traits in the three P treatments. Of these, 11 QTLs under low P condition on chromosomes 2BL, 4BS (2 QTLs), 4DS (2), 6BL (2), 7AL (2), and 7BL (2) for root length (RL), root tip number (RTN) and ratio of root to shoot dry weight (RRS) explained 4.6 - 20.4% of the phenotypic variances. QRRS.caas-4DS (16.64 - 30.66 Mb) was detected in all three P treatments and accounted for 8.4 to 20.4% of the phenotypic variances. Seven QTLs clusters (C1 to C7) were mapped on chromosomes 3DL, 4BS, 4DS, 6BL, 7AS, 7AL and 7BL, of which five (C3 to C7) were detected under low P condition. Cluster C5 on chromosome 7AS (AX-109955164 - AX-109445593) played the key role in modulating RL, RTN and ROSA, with the favorable allele coming from Zhongmai 895. SNPs closely linked to QTLs and clusters could be used for improving root nutrient-use efficiency traits in future breeding.

Background

Phosphorus (P) is an important macro-element for ensuring plant morphogenesis, productivity and grain quality [1]. P as phosphate is immobile in most of the soil types that make its application on the soil surface less beneficial for plants. While efficient uptake of P from deep soil depends on plant's underground organs. P deficiency causes abnormal physiological and biochemical metabolism during plant growth [2]. In crops, an efficient root system is crucial for P-uptake; increase in root to shoot ratio in most of the elite cultivars helps to access P from deep soil or grow longer root hairs to exploit the spatial characteristics of soil [3]. Therefore, optimization of root-related traits could provide a promising avenue to enhance P uptake and increase grain yield [4].

Significant genetic diversity of root-related traits under different nutrient conditions has been considered very important [5, 6]. These variations could be exploited to improve nutrients uptake by wheat plants and provide a sustainable solution for developing elite cultivars [2, 7, 8]. In wheat, QTLs have been detected for root traits under different P treatments across the 21 chromosomes [9, 10]. Despite the many genetic interactions which have been determined for the root biomass and root system architecture traits, but still few loci were reported with major effects [11, 12]. Nowadays, construction of high-density genetic maps has increased the accuracy of quantitative genomic analysis. These maps can help to identify useful loci for root morphological and P-uptake related traits [13].

However, the characterization of root traits under normal field conditions is difficult; traditional methods such as soil columns and soil cores are time-consuming and laborious for screening of large populations

[14, 15]. Artificial systems like sand, germination paper and hydroponic based cultures have been used as proxies for characterization of root traits [4, 16]. Hydroponic culture with digital imaging has given new insight about different aspects of root development compared with sand culture and germination paper experiments. Moreover, hydroponic technique can be applied for rapid screening of large populations. Several important loci and QTL clusters related to root biomass and root system architecture were reported similar in both hydroponic and field trials conditions [11, 12, 17]. There is not report regarding cloning of QTLs for P-uptake related root traits or P uptake efficiency yet. The 660K SNP array in wheat has greatly improved the density of genetic maps for QTL analysis compared with the earlier 90K Array [18, 19]. This could increase the chance for identification of true loci for complex traits.

The aims of this study were to evaluate phenotypic diversity of Yangmai 16/Zhongmai 895 derived doubled haploid (DH) population for root system architecture and biomass related traits in different P treatments at seedling stage using hydroponic culture, and to identify QTLs for root system architecture and root biomass-related traits under low and high P conditions using 660K SNP array based high-density genetic map.

Methods

Plant materials

The panel of 198 DH lines from the cross of Yangmai 16/Zhongmai 895 were evaluated for root-related traits in hydroponic culture. All the materials used in this study were provided in a temperature-controlled greenhouse in National Wheat Improvement Centre, Institute of Crop Sciences, Chinese Academy of Agricultural Sciences from March to April 2016, and authenticated by Associate Professor Yonggui Xiao (Chinese Academy of Agricultural Sciences), and available after approval. The female parental Yangmai 16 is a spring wheat cultivar with drought resistance attributes and cover the largest planting area in the Middle and Lower Yangtze River region. Zhongmai 895 is a facultative cultivar and widely cultivated in southern parts of the Yellow and Huai Valleys. Characterized by high yield potential with drought and heat resistance ability strong root early vigor.

Hydroponic culture and experimental design

Hoagland's nutrient solution was used [20], and three P levels were kept at zero (control), low and high P contents (KH_2PO_4 0, 0.005, 0.25 mmol/L, respectively). KCl at 0.35, 0.345 and 0.10 mmol/L, respectively, was added in the three treatments to maintain a common concentration across treatments [21](Table S1). The experiments were conducted in randomized complete blocks (RCBD), with three replications from March 15 to April 28, 2017, and 30 healthy seeds of each line were used for each treatment.

The seeds of each line were sterilized for 15–20 minutes in a 10% H_2O_2 solution. After rinsing 5–6 times in sterilized water, seeds were placed on moisturized germination paper in glass Petri dishes, crease-side down and left for 36 h in darkness for initial germination. After the early appearance of germination seeds were transferred to sand (2 mm diameter) box in a dark environment for seedling growth at 24°C

for 72 h. The sand box was kept under a constant environment room (12-h photo-period: 16°C day and 13°C night, light intensity at 400 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PAR while relative humidity at 70%) where subsequent phenotyping was to be conducted for their growth. Three uniformly sprouted seeds with ~5 mm in roots length were transferred to holes in trays (the seedling was holed with a sponge), and were placed on plastic tanks (660×480×280 mm) containing 20 L of nutrient solution; the solution was renewed every three days. After 10 days (two-leaf stage) plants were harvested and placed in 30% ethanol prior to imaging.

Trait measurements

Five root system architecture (RSA) traits, viz. root length (RL), root volume (RV), root diameter (RD), root tip number (RTN), root surface area (ROSA) were captured through images using a scanner (Perfection V700/V750 2.80A; Epson, China). Images were analyzed by using the software RootNav V1.7.5 which was operationally semi-automated [22]. Root biomass-related traits (RBT), including shoot dry weight (SDW) and root dry weight (RDW) were measured after oven-drying for 72 h at 70°C (mg/plant). Total dry weight (TDW) was estimated as the sum of SDW and RDW, and ratio of root to shoot dry weight (RRS) was measured as ratio between RDW and SDW.

SNP genotyping and QTL analysis

The DH lines and parent cultivars were genotyped through Wheat 660K SNP array synthesized by Affymetrix and commercially available from Capital Bio Corporation (Beijing, China; <http://www.capitalbio.com>). Genetic map was contacted by Wang et al. [23] from our lab. Briefly, markers with no polymorphisms between parents, severely distorted segregations, and missing rate greater than 20% were removed in the subsequent linkage analysis. Finally, 10,242 markers each representing a bin site were selected to construct the linkage map of Yangmai 16/Zhongmai 895 population, which comprised 25 linkage groups, covering all 21 wheat chromosomes. Among them, chromosomes 1B, 2B, 4A and 7A consisted of two linkage groups, and the remaining chromosomes were with only one linkage group. Inclusive composite-interval mapping was used for QTL analysis in IciMappingV4.1 software [24], and averaged data from the three replicates were used for QTL detection. The SNP genotypes of Yangmai 16 were defined as A, and those of Zhongmai 895 as B. Alleles from Yangmai 16 reduced trait values when the additive effects were negative. Kosambi mapping approach was used to convert recombinant frequencies into distance map [25]. Locations of QTLs for the root traits were detected by inclusive composite interval mapping-additive (ICIM-ADD) by using same software as for the QTL analysis. The threshold for significant QTL of each trait was demarcated by 1000-permutations at $P = 0.05$ [26], and minimum LOD score at 2.5 with walking speed at 1.0 cM. Joint QTL analysis for closely linked pleiotropic QTL was performed using the general linear model scripted in lm package of R software. Phenotypic variance explained by each QTL was calculated as demonstrated in Li et al. [27].

Statistical analysis

Pearson's correlations analysis among the traits were estimated using averaged data from each replicate. Significance of variances among DH lines, treatments and interactions between genotypes and treatments (G×T) was calculated using following mixed linear model and considered significant at $P < 0.05$.

$$Y = X\beta + Z\mu + ge + \varepsilon \quad (1)$$

where Y is demonstrated as the response from fixed (β) and random (μ) effects with random error (ε), ge is the genotype × environment effect while X and Z illustrate fixed and random effects, respectively. Broad sense heritabilities for all traits were estimated using genotypes as a random effect following [28].

$$h^2 = \sigma_g^2 / (\sigma_g^2 + \sigma_{gt}^2 / r + \sigma_\varepsilon^2 / rt) \quad (2)$$

where σ_g^2 , σ_{gt}^2 and σ_ε^2 represent genotype, genotype (DH line) × P treatment interaction and error variances, respectively, while t is indicated P treatments and r is replicates. The R package was used for all statistical analyses [29].

Results

Phenotypic variation and correlations among traits under P treatments

Data for all nine traits were normally distributed across the three P treatments (Fig. S1). Under low P condition, Zhongmai 895 showed higher RL, RV, ROSA, RDW, TDW and RRS, but lower RD, RTN, and SDW than Yangmai 16. Except for RD and RRS in the high P treatment, Yangmai 16 had higher RL, RV, RTN, ROSA, SDW, RDW and TDW than Zhongmai 895 (Fig. S2).

Phenotypic variances among the DH lines were significant ($P < 0.0001$). Transgressive segregations across P treatments were observed for most of traits (Fig. S2; Table 1). The average values of the DH lines for RL, RV, RTN, and RRS were higher than parents in the low P treatment, indicating positive effects for root vigor from both parents (Fig. 1–S2). Broad-sense heritabilities of nine traits were ranged from 0.76 to 0.91 (Table 1).

RSA and RBT traits were correlated significantly ($r = 0.59$ to 0.98 at all three P levels). However, RD was negatively correlated with RL, RTN and ROSA ($r = -0.23$ to -0.69) (Fig. 2).

QTLs for root system architecture traits

Nineteen QTLs from the three P treatments were identified for RSA traits RL, RV, RTN and ROSA on chromosomes 1BL, 2BL, 2DL, 3DL, 4BS, 6AL, 6BL (2), 6DS, 7AS (5), 7AL (3) and 7BL (2) (Table 2). Among them 6 QTLs were detected for the zero control, and 7 in the low and 6 in the high P treatments with the phenotypic variances explained of 45.1, 48.0, 53.7%, respectively. Seventeen QTLs on chromosomes 2BL, 2DL, 3DL (2), 4BS (3), 6AL, 6BL (3), 6DS (2), 7AS (2), 7AL (2) conferred positive additive effects contributed by Zhongmai 895 (Table 2). In the low P treatment, three QTLs were identified for each of RL

and RTN, explaining 20.7% and 21.7% of phenotypic variances, respectively. RL and RTN were co-located on chromosomes 6BL, 7AL and 7BL. In addition, Zhongmai 895 possessed positive alleles on 6BL and 7AL for increased phenotypic values (Table 2).

QTLs for root biomass-related traits

Fifteen QTLs for RBT traits were identified on chromosomes 3AS (3), 3DL, 4BS (5), 4DS (4), 6BL and 6DS (Table 2). Two, 4 and 9 QTLs were identified in the zero, low and high P treatments, and explained 34.0, 42.8 and 67.6% of the phenotypic variances, respectively. A stable QTL (*QRDW.caas-4BS*) was identified under both low and high P conditions, explaining 8.1 to 17.7% of the phenotypic variances for RDW. A pleiotropic QTL on chromosome 4DS in interval *AX-109816583 - AX-109478820* (16.64 - 30.66 Mb) detected in the low P treatment for RDW co-located with 3 QTLs in all three P treatments for RRS explained 7.1 to 20.4% of the phenotypic variances (Table 2).

QTL clusters

Fifteen QTLs in seven clusters (C1 to C7) for different traits in all three P treatments were identified in the same or close marker intervals (Fig. 3). QTL clusters were located on 3DL, 4BS, 4DS, 6BL, 7AS, 7AL and 7BS chromosomes, respectively. Of these, C1 was on 3DL for SDW and RTN under high P treatment. C2 for RV and RRS on 4BS was detected in a 0.31 Mb interval between SNPs *AX-109491270* (21.79 Mb) and *AX-108815849* (21.42 Mb). C3 on 4DS comprised QTLs for RDW and RRS. QTL in clusters on 4B (16.64 - 30.66 Mb) and 4D (32.42 - 37.86 Mb) were at or very near to reduced plant height gene loci *Rht-B1* (30.8Mb) and *Rht-D1* (18.9Mb), respectively. C4, C6 and C7 involved the same traits (RL and RTN) on chromosomes 6BL, 7AL and 7BL. Joint QTL analysis reveal that, QTLs presented in four clusters. i.e. C3 (RDW and RRS), C4 (RL and RTN), C5 (RL, RTN, ROSA) and C7 (RL and RTN) were identified as pleiotropic QTL under different P levels (Fig. 3). C5 on 7AS (*AX-109955164-AX-109445593*) affected RL, RTN and ROSA, with the favorable allele contributed by Zhongmai 895 (Fig. 3).

Discussion

Evaluation of traits related to root system architecture and root biomass

Using a hydroponic-based phenotyping pipeline the root biomass and root system architecture-related traits of a DH population were measured in a cost-effective and rapid manner. Previous studies found strong correlations between such laboratory-based experiments and field data [30, 31]. Most of the traits were higher under the high P treatment compared with zero and low P treatments. High heritabilities and significant genetic variances for root system architecture and biomass traits indicated that these traits could be used as primary selection criteria for enhancement of P uptake [12, 13]. The present results corroborated earlier findings for genetic variances of root-related traits under different treatments [6, 32, 33].

Correlation between root traits at variable P levels

P deprivation restricts the growth of main roots while increasing the lateral roots elongation, numbers of root hairs [34] (Gu et al. 2016) and leads to higher ratio of root to shoot that change the root architecture [10] (Ayalew et al. 2015). In this study, RSA traits RL, RV, RTN and ROSA, and RBT traits RDW and RRS showed higher growth and highly positive correlation between each other at the low P level (Fig. 1, 2). This trend was contributed by Zhongmai 895, which also had longer roots, high root tip number and high RRS in the low P treatment. High accumulation of SDW under high P conditions and greater RRS under low P were observed in Yangmai 16 (Fig. S2). SDW and RRS were negatively correlated across treatments (Fig. 2), although previous work found that low P led to reduced root biomass and had a significant impact on root system architecture traits [4, 13, 35].

A significantly negative correlation ranging from -0.23 to -0.69 for RD and RL, RTN and ROSA in all three P treatments indicated a negative association of RD with P uptake across all DH lines (Fig. 2). A similar trend also observed for Zhongmai 895 under high P treatment (Fig. S2).

QTLs under phosphorus treatments

Significant variances among genotypes allowed us to explore genomic regions associated with the observed traits [4]. Several QTLs were identified previously using hydroponic culture, which showed a vital role in nutrient uptake and a positive correlation with yield-related morphological traits. Here we identified 34 QTLs on 1B, 2B, 2D, 3A, 3D, 4B, 4D, 6A, 6B, 6D, 7A and 7B chromosomes across the P treatments (Table 2). Some QTLs were already reported for root system architecture and root biomass-related traits [12, 36]. New loci closely linked with *AX-109273188* (16.63 Mb) on 3AS, *AX-94471535* (704.88 Mb) on 6BL, *AX-109109966788* (725.54 Mb) on 7AL and *AX-109289805* (705.84 Mb) on 7BL showed significant influence for root growth.

The genetic diversity for root vigor under low P conditions that could potentially improve P acquisition efficiency, and described some QTLs for RBT under low P conditions [11]. We detected QTLs on 2BL, 4BS, 4DS, 6BL, 7AL and 7BL showing high phenotypic variances for RTN, RRS and RL under low P. (Table 2). Previously, Su et al. [9, 35] evaluated two DH populations in pot and field experiments and reported that common QTL on chromosome 4B associated with shoot biomass and tiller number were potentially important for P efficiency. Here, QTL in same genomic region of the 4B chromosome were detected for RDW and RRS (Table 2). Interactions between root-related growth traits and *Rht* genes were reported as important in early vigor and nutrient uptake [11, 37, 38, 39]. These demonstrated contrasting impact of *Rht* genes on seedling traits under different nutrient conditions. In this study, two important QTLs mapped on 4B (16.64–30.66 Mb) and 4D (32.42–37.86 Mb) in low P corresponding to *Rht-B1b* (30.9Mb) and *Rht-D1b* (18.9Mb), respectively, had negative impact on RRS for both parents and DH population in contrast with a previous report [38].

QTLs for RTN, RL and SDW were identified on 2DL and 6BL under low P condition. These QTLs had been also demonstrated for root related traits under P sufficiency conditions on 2D and 6B in pot trials [35] and hydroponic culture [4]. Five QTLs on chromosome 7AS explained higher phenotypic variances of 4.6 to 11.9% for RL, RTN and ROSA. Four of these QTLs detected under high P conditions negatively influenced

root elongation, RTN and ROSA and the remaining QTLs on 7AL affecting RTN had a role in increasing RTN in low P condition (Table 2). RL, RTN and ROSA are important traits for nutrient uptake and early seedling vigor. Closely linked QTLs *QRL.caas-7BL* and *QRTN.caas-7BL* near *AX-109289805* (705.84 Mb) could be important for early vigor under P deficient conditions, whereas their strong relationship with kernel number per spike was earlier demonstrated by Zhang et al. [40]. SNPs linked with QTLs for these traits on 7A and 7B stably detected in different nutrient conditions might be of great value for wheat breeding.

QTL clusters

Previously high-density physical mapping results demonstrated about 85% of gene expression and also has many cluster distributions in wheat genome that covered 5 to 10% of chromosome regions [41]. In wheat, many QTL clusters were reported in several studies [42–46]. In the present study, seven clusters were identified in three different P treatments (Fig. 3). Clusters C3, C4, C5 and C7 had pleiotropic QTLs for root system architecture and biomass-related traits under different P treatments, whereas QTLs in other clusters contained closely linked multiple genes without pleiotropic effects. Clusters C2 and C3 on chromosomes 4BS and 4DS were linked with reduced plant height genes. Cluster C4 on 6BL had QTLs controlling RL and RTN and previously were reported for thousand grain weight [13]. Cluster C5 on chromosome 7AS (*AX-109955164* - *AX-109445593*) affecting RL, RTN and ROSA was identified for the first time in the present study and SNP linked with this cluster can be used for future wheat improvement. Whereas cluster C7 on chromosome 7BL containing QTLs for RL and RTN was also reported for RL and SDW under P-deficient condition in previous studies [4, 13](Fig. 3). The SNPs tightly linked to QTLs or QTL clusters identified in the present study can be converted to KASP assays and effectively used for MAS to improve nutrient-use efficiency in wheat breeding.

Conclusions

Thirty-four QTLs with significant phenotypic variations for root system architecture and biomass-related traits were identified using high-density genetic map constructed from 660k SNP array and cost effective hydroponic-based phenotyping pipeline. Four QTLs on chromosomes 6BL (2) and 7AL (2) identified in low P treatment showed positive additive effects contributed by Zhongmai 895, indicating that Zhongmai 895 could be used as parent for P-deficient breeding. A stable QTL *QRRS.caas-4DS* (16.64–30.66 Mb) was also detected across the three P levels, accounted for 8.4 to 20.4% of the phenotypic variances, which could be used for speedy selection of genotypes for P-uptake. Among the seven QTLs clusters, C5 identified on chromosome 7AS (*AX-109955164*-*AX-109445593*) affecting RL, RTN and ROSA could be vital for improving the nutrient use efficiency of roots. The identified chromosome regions, particularly the QTL clusters could be used for molecular marker-assisted selection in future breeding.
