Abstract

Background: Critically ill patients are frequently suffering from vitamin C deficiency. Previous studies showed that high doses of vitamin C administration had conflicting results on clinical outcomes in patients with severe sepsis, burns and trauma. Because of high incidence and morbidity/mortality with severe pneumonia, we aimed to investigate the effect of administration of high dose vitamin C in critically ill patients with severe pneumonia.

Methods: Eighty critically ill patients with pneumonia were enrolled in this randomized double blinded clinical trial. Patients with CURB-65 score >3 , one major criteria, or ≥ 3 minor criteria were considered as severe pneumonia. Patients were randomly assigned to intervention or placebo groups receiving standard treatment plus 60 mg/kg/day vitamin C as continuous infusion or normal saline in the same volume correspondingly for 96 hours. Serum levels of vitamin C were noted at baseline and 48 hours after vitamin C administration. Duration of mechanical ventilation, ICU length of stay, $\text{PaO}_2/\text{FiO}_2$ and mortality rate were noted for all patients till the 28th day. Any complications related to vitamin C administration were recorded. (IRCT registration number: **IRCT20190312043030N1**, Registration date: **2019-08-26**, seied hadi saghaleini).

Results: Duration of mechanical ventilation and vasopressor use were significantly lower in intervention group (p : <0.001 and 0.003 , respectively). Baseline levels of vitamin C in both groups did not have significant difference but its levels increased in intervention group and decreased in control group during the study period. Mortality rate insignificantly decreased in intervention group (p : 0.17). Three patients showed hypotension and tachycardia during the administration of vitamin C which was self-limited with decreasing the dose of vitamin C.

Conclusion: Our results showed that the intravenous administration of a relatively high dose of vitamin C to critically ill patients with severe pneumonia was safe and could decrease the inflammation, mechanical ventilation duration and vasopressor use without any significant effect on mortality.

Background

Plasma levels of vitamin C are usually decreased in the critically ill patients with sepsis, burn, major surgeries, trauma and any disease accompanied with immune dysfunction and inflammation¹. This reduction in Vitamin C level is contributed to lower intake and higher metabolism in critically ill patients². Based on the modulation of oxidative stress, endothelial protection, and involvement in organ's functionality and energy metabolism, vitamin C represents interesting therapeutic approach in critically ill patients as a safe and low-cost nutrient. Recently, there are many published trials about the positive effect of combination therapy of high dose vitamin C, thiamin and fludrocortisone in septic patients. They showed that this combination which targeted multiple components of host response could synergistically restore the immune dysfunction; however, future studies showed different results regarding morbidity and mortality^{3,4}. Based on the high incidence of pneumonia in critically ill patients and its effect on mortality,

it seems that the effects of vitamin C on respiratory infections are also important at the level of fundamental concepts. Corkovic et al. showed that the serum level of vitamin C was significantly decreased in patients with acute pneumonia and patients with exacerbation of COPD. They also showed a negative correlation between level of vitamin C and laboratory markers of inflammation⁵. Results of a systematic review in 2004 showed that vitamin C substantially reduced the incidence or severity of respiratory infections but there were many questions about heterogeneity of trials, route and dose of vitamin C administration, and sample size of the studies⁶. Results of a recently published Cochrane systematic review showed skepticism about the effect of vitamin C supplementation for prevention and treatment of pneumonia. They also emphasized to conduct better-quality studies for assessment of the role of vitamin C supplementation in the prevention and treatment of pneumonia⁷. Considering the dosing and route of administration is very important regarding vitamin C therapy in critically ill patients. It is unclear whether the dosing strategy should attempt to achieve normal or supraphysiologic plasma vitamin C levels. On the other hand, intravenous dose is necessary and enteral uptake because of gut dysfunction is unpredicted⁸. Recent trials showed that high dose vitamin C (2-3 g/day) is recommended to restore normal plasma concentration^{9,10}. Studies that used high doses of vitamin C (3-10 g/day) showed advantageous effects on biological and clinical outcome in critically ill patients^{11,12}. Based on the safety profile and molecular characteristics of vitamin C in critically ill patients and controversial results of previous studies, we aimed to evaluate the effect of high dose intravenous administration of vitamin C on mortality of critically ill patients.

Methods

After obtaining ethics committee approval and getting informed consent from patients or their legal guardian (When the level of consciousness of patients was low), 80 critically ill patients with pneumonia were enrolled in this randomized double blinded clinical trial. (Trial registration number: IRCT, 20190312043030N1). All patients who were admitted to intensive care unit (ICU) of a university-affiliated hospital in northwest of Iran with the diagnosis of severe pneumonia were enrolled in this study from May 2019 till Dec 2019. We defined nosocomial pneumonia as the pneumonia in patients admitted to the hospital for >48 h. Among nosocomial pneumonias, ventilator-associated pneumonia (VAP) develops in intensive care unit (ICU) patients who have been mechanically ventilated for at least 48 h. Patients with severe nosocomial pneumonia who require mechanical ventilation during their treatment after the onset of infection do not meet the definition of VAP¹³. Patients with CURB-65 score >3, one major criteria, or ≥ 3 minor criteria were considered as severe pneumonia. Exclusion criteria were age less than 18 and more than 80 years old, renal insufficiency, history of vitamin C usage during past 48 hours, allergy to vitamin C, pregnancy or breastfeeding, life expectancy of less than 24 hours; previously complicated with end-stage lung disease, end-stage malignancy, glucose-6-phosphate dehydrogenase deficiency, diabetic ketoacidosis, active kidney stone disease, and participation in another clinical trial at the same time and immunocompromised patients. Severity of pneumonia was diagnosed based on CURB-65 (confusion, uremia, respiratory rate, BP, and age ≥ 65 years) and PSI index. We will construct 6 blocks in AABB, BBAA, ABAB, BABA, ABBA and BAAB using four blocks. We will assign 1 to 6 for each block. Then, using the

random number table, based on the sample size, 20 units of 4 blocks will be selected so that we consider having 40 people in control group (A) and 40 people in intervention group (B). Therefore, we will do block randomization. In this study, patients, clinical caregivers, and data analyzers will not aware of grouping.

Patients were randomly assigned to one of the following groups: intervention group in which patients received standard treatment plus 60 mg/kg/day vitamin C as continuous infusion for 96 hours. Patients in control group received standard treatment plus intravenous infusion of normal saline as the placebo in the same volume. Standard pneumonia therapy included of empirical antibiotic therapy before the administration of appropriate antibiotic based on the bacteria isolated on laboratory testing, as well as adjunct respiratory therapy. The types of antibiotics were started empirically for coverage of possible gram negative, gram positive and anaerobes with simultaneously performing cultures for source identification. Mostly our used antibiotics for empirical therapy were carbapenems/piperacilline tazobactam plus a fluoroquinolone with or without vancomycin/linezolid. After obtaining the results antibiotics were changed as targeted therapy based on culture and microbiological results.

Patients' demographic characteristics were recorded during the study period. Sequential organ failure assessment (SOFA) was assessed during the study and acute physiologic and chronic health evaluation (APACHEII) was assessed on the first day of ICU admission. We evaluated patients for any complication during intravenous infusion of vitamin C including hypotension (systolic blood pressure less than 70 mmHg or 30% decrease compared to the baseline), tachycardia (increase more than 20% compared to baseline or heart rate more than 120/min), nausea/vomiting and hypernatremia. If any of the aforesaid complications was seen, the rate of administration of vitamin C was decreased by 50% and if it continued, the infusion was stopped. Serum level of vitamin C were noted at baseline and 48 hours after vitamin C administration. Duration of mechanical ventilation, ICU length of stay, $\text{PaO}_2/\text{FiO}_2$ and mortality rate were noted for all patients until the 28th day.

Sample size was calculated based on the α -error of 5% and power of 80% as 36 subjects per group which was increased to 40 in each group. Data were analyzed using SPSS 17 software and reported as mean \pm standard deviation for the continuous variables, and percentage for discrete variables. Non continuous variables were analyzed with Chi-square and continuous variables were analyzed with T-test. Organ dysfunction indices based on SOFA/APACHE scores were compared by regression correlation and T-test. A P-value of less than 0.05 was considered significant.

Results

A total of 141 critically ill patients with severe pneumonia were eligible for this study. Fifty-eight patients were excluded from the study and 83 patients were randomized into two groups. Three patients were withdrawn due to mortality before 48 hours and patient refusal to participate in the study (Fig. 1). Finally, two groups of 40 patients were analyzed in this randomized trial. Mean age of patients was 57.95 ± 12.9 years with the male/female ratio of 46/34. Frequencies of hospital acquired pneumonia, community acquired pneumonia and ventilator associated pneumonia were 34, 21 and 25, respectively. Demographic

characteristics of patients during the study are shown in Table 1. Vasopressor was used in 48 patients and the only used vasopressor was norepinephrine. Duration of mechanical ventilation and vasopressor use was significantly less in intervention group ($p < 0.001$ and $= 0.003$, respectively). Our results showed that SOFA score decreased during study in both groups but the level of this reduction was more in intervention group than the control group. Moreover, its difference was significant at 72 and 96 hours between two groups ($p = 0.01$ and < 0.001 , respectively). The results were the same for procalcitonin, C-reactive protein and $\text{PaO}_2/\text{FiO}_2$ levels in two groups after 24 hours. Baseline levels of vitamin C in both groups didn't have significant difference but the level increased in intervention group and decreased in control group during the study (Table 2). Totally, 17 patients died in this study which 6 of them were in intervention group. Results showed that mortality was insignificantly lower in intervention group ($p = 0.17$). Three patients showed hypotension and tachycardia during the administration of vitamin C which was self-limited by decreasing the dose of vitamin C. The frequency of AKI in two groups didn't have a significant difference ($p = 0.12$)

Discussion

The main finding of this study is that administration of high dose intravenous vitamin C in critically ill patients with severe pneumonia is safe. This treatment is associated with decreasing in duration of mechanical ventilation and vasopressor usage and also improvement in oxygenation with concomitant

decrease in pulmonary severity indices without any significant decrease in ICU length of stay and mortality.

Vitamin C is known to be used for treating of cancer and respiratory viral infections. However, new information regarding the pharmacokinetic properties of vitamin C and results of recent studies have raised interest in the utilization of high-dose vitamin C in critically ill patients¹⁴. Previous studies showed that treatment with vitamin C decreased procoagulant and proinflammatory markers in respiratory system which resulted in lower lung injury¹⁵. Vitamin C can also diminish the sequestration of neutrophils, improve alveolar fluid clearance, and maintain lung barrier function¹⁶. Moreover, vitamin C can counter oxidative stress by decreasing hydrogen peroxide, superoxide anion, and nitric oxide levels¹⁷. So, vitamin C not only increases bacterial killing potency in early stages but also modulates the immune response in later stages of disease. These evidences were supported by our results which showed that vitamin C administration significantly diminished the inflammatory and severity markers of critically ill patients¹⁸. Results of an interesting study showed that nearly 70% of critically ill patients had hypovitaminosis C despite receiving standard ICU nutritional support which emphasized the importance of its substitution in critically ill patients². Results of a recently performed RCT showed that administration of 15g/day of IV vitamin C for 96 hours in 167 patients with ARDS due to sepsis showed a decreased in mortality¹². This trial used the same duration but much higher doses of vitamin C compared to our trial with a larger sample size; this can explain its results regarding mortality. One important point regarding administration of vitamin C is the fact that it is not possible to restore normal levels with oral supplementation due to saturable absorption kinetics and reduced absorption in critical illness; so, intravenous administration is necessary. The other point is the time to start vitamin C therapy. The earlier the treatment is started, the better are the results. Delayed starting in patients evolves into a phase of irreversible multi-system organ failure and at this time treatment may be futile. Hemila et al in a recently published meta-analysis evaluated six trials of vitamin C administration in ICU. In three trials in which patients needed mechanical ventilation for over 24 hours, vitamin C shortened the duration of mechanical ventilation by 18.2% (95% CI 7.7% to 27%; $p = 0.001$). They recommended that the effect of vitamin C should be investigated in more trials based on low cost and decrement in ICU length of stay¹⁹. Cai et al. showed that vitamin C can improve the outcome in pneumonia due to influenza virus by its effect on inhibition of CORT synthesis which reduces the susceptibility to influenza viral infection²⁰. Regarding critically ill COVID-19 patients with pneumonia with a high mortality rate, it seems that timely administration of high dose intravenous vitamin C has been particularly effective by inhibiting the production of cytokines storm due to COVID-19²¹.

The present study has several limitations. It was a single center design with relatively small sample size in a medical ICU. The resulting low power of study may have limited our ability to detect significant effects of the vitamin C protocol on the primary and secondary outcome variables. Also, 15 patients in control group and 10 patients in intervention group received corticosteroid for shock reversal, resulting in diminution in vasopressor dose which could interfere in our results. Thus, the results of this study cannot be generalized to all critically ill patients with pneumonia, different comorbidities or surgical problems. It

is important not to make strong conclusions about this trial intervention, whether the results are positive or not. Instead, data from this study should be used to design larger confirmatory studies to provide reliable evidence about the effect of vitamin C administration for prevention of pneumonia in critically ill patients.

Conclusion

Finally, our results showed that the intravenous administration of a relative high dose of vitamin C to critically ill patients with severe pneumonia is safe and can decrease the inflammation, mechanical ventilation duration, and vasopressor use without any significant effect on mortality. These results would probably be different with a greater increase in the sample. However, based on the aforesaid limitation, future large randomized controlled studies are needed to evaluate the optimal dose and duration, and probable adverse effects of vitamin C in critically ill patients with severe pneumonia.
