Abstract

Objective: The objective of this study was to investigate associations between Energy-Adjusted Dietary Inflammatory Index (EDII) with quality of life and serum inflammatory markers.

Results: This cross-sectional study was performed on 280 adults healthy overweight and obese aged between 18 and 50 years old that was selected from 20 various health centers by a multistage cluster random sampling method. The mean age of the study participants was 36.30±8.05 years. Analyses were performed using multivariable linear regression, adjusting for age, weight, physical activity, smoking status, economic status, and employment status. Linear regression analysis demonstrated that E-DII were significantly associated with certain the quality of life criteria, such as physical function, mental health, and vitality ($\beta = 5.58$, 95% CI 0.72, 10.43, $p = 0.024$, $\beta = 16.88$, 95% CI 10.75, 23, $p < 0.0001$ and $\beta = 14.29$, 95% CI 9.48, 20.36, $p < 0.0001$, respectively). No significant associations were observed between EDII and serum level hs-CRP. It was found that dietary inflammatory potential decreased some quality of life measurements and levels in overweight and obese Iranian women.

Introduction

Obesity and overweight are some of the most prominent public health problems that mean excessive fat accumulation, defined as BMI (25-29.9) and BMI $\geq$ 30 respectively, according to WHO definitions.[1, 2]. Overweight and obesity are common in Iran and are significantly more prevalent among women than men, it has been found that 42.9 percent of men and 56.9 percent of women were overweight or obese and 10.9 percent of men and 24.5 percent of women were obese in Iran.[3]. Accumulating evidence indicates that obesity is closely associated with an increased risk of cardiovascular disease (CVD), hypertension (HTN), type 2 diabetes mellitus (T2DM), strokes, and poor health quality of life (HQOL).[4].

In addition to medical complications, overweight and obesity is accompanied by a decline in health-related quality of life factors, such as physical functioning, psychosocial functioning, and emotional well-being.[5-8]. The concept of quality of life (QoL) is a complex, multifaceted construct that includes various aspects, such as physical health and psychological health.[9].

The results of recent studies show that obese people with lower BMI have a higher quality of life than those with higher BMI scores.[10]. The rising prevalence and health-related consequences of obesity make it a public health concern all over the world.[11, 12]. Furthermore, obesity is typically associated with a chronic state of systemic low-grade inflammation since adipocytes result in the expression of cytokines such as Hypersensitive serum C-reactive protein (hs-CRP), the serum levels of six inflammatory biomarkers (Interleukin1beta (IL-1$\beta$), Interleukin 4 (IL-4), Interleukin 6 (IL-6), Interleukin 10 (IL-10), Tumor necrosis factor-alpha (TNFa) and C-reactive protein (CRP)) as seen by the dietary inflammatory index (DII) dependent on the intake of 45 unique foods and nutrients.[13, 14]. Recent studies have shown reliable associations between diet and systemic inflammation so that diet can play a major and significant role in the quality of life.[15, 16]. The energy-adjusted dietary inflammatory index is a validated method developed to characterize dietary inflammatory potential.[17]. It that seems increased inflammatory factors could affect most components of quality of life such as physical health and psychological health.[18]. Given all the above, it was hypothesized that greater adherence to an anti-inflammatory diet would be associated with lower low-grade inflammation and greater quality of life in overweight and obese patients. To the
researchers’ knowledge, this is the first study investigating the relationship between energy-adjusted dietary inflammatory index and quality of life.

**Methods**

**Study Design and Participants**

The current cross-sectional study was conducted among overweight and obese women who attended health centers in Tehran, Iran, in 2018. A random sample of 280 adults healthy overweight and obese aged between 18 and 50 years old women was selected from 20 various health centers by a multistage cluster random sampling method. Eligible criteria included body mass index in the range of 25-40 kg/m² and good general health. Exclusion criteria included: a history of cardiovascular disease, hypertension, diabetes mellitus, hepatic or renal disease, and alcohol, smoking usage, medicine usage other than birth control pills, pregnancy or lactation, menopause, following a specific diet or bodyweight fluctuation over the past 1 year. Participants whose reported daily energy intake less than 800 kcal/d or more than 4200 kcal/d were also excluded. The study protocol had an ethical approval (ID: 95-03-161-33142), which was approved by the Ethics Commission of the Tehran University of Medical Sciences. Informed consent was obtained from all participants.

**Dietary Assessment**

Participants’ dietary intake over the past year was assessed using a valid and reliable semi-quantitative food frequency questionnaire (FFQ) self-reported[19]. This FFQ consists of 147 food items with standard serving sizes, and participants were asked to specify their consumption frequency for each food item for each item based on 4 predefined groups, including daily weekly, and monthly frequent consumption. The consumed foods portion sizes were converted to grams using household measurements[20]. Then, nutrient and energy intakes were computed using NUTRITIONIST IV software (version 7.0; N-Squared Computing, Salem, OR), which was tailored for Iranian foods. For calculating EDII, all nutrient values were adjusted for energy intake using the residual method.

**Dietary Inflammatory Index Calculation**

Since not all food items are the same in all types of food frequency questionnaires, we should calculate the DII score according to the data of foods which are available in our food frequency questionnaire with the change in the method of Shivapa et al. To calculate EDII for the participants of this study, the dietary data were first linked to the regionally representative world database, which provided a robust estimate of a mean and standard deviation for each parameter. These then become the multipliers to express an individual's exposure relative to the 'standard global mean' as a z-score. A z-score for each food consumed was calculated by subtracting the 'standard mean' from the actual food parameter value and divided by its standard deviation. Next, to minimize the effect of 'right skewing', this value was then converted to a centered percentile score, which was then multiplied by the respective food parameter inflammatory effect score to obtain the subject's food parameter-specific EDII score. All of the food-parameter-specific EDII scores were then summed together to create an overall EDII score for every subject in the study [21]. In total, the EDII computed based on this study's FFQ includes data on 29 of the 45 possible food variables composing the EDII: energy, carbohydrate, protein, fat, fiber, cholesterol, trans fat, SFAs, MUFAs, PUFAs, omega-3, omega-6, niacin, thiamin, riboflavin, vitamin B-6, vitamin B-12, iron, magnesium, selenium, zinc, vitamin A, vitamin C, vitamin D, vitamin E, folic acid, b-carotene, caffeine, onion, and tea. The EDII was analyzed as a dichotomous variable, categorized based on the median value of the EDII. DII values were categorized according to
the median (0.05). EDII ≤ 0.05 is considered an Anti-inflammatory diet group and, EDII > 0.06 is considered a pro-inflammatory diet.

Quality of Life Assessment

The SF-36 is a short-form, self-administered quality of life scoring questionnaire. It consists of 36 questions, 35 of which are compressed into eight multi-item scales including physical functioning (PF), role physical (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role emotional (RE), and mental health (MH) [22, 23]. The SF-36 also includes a question self-evaluating health changes in the past year (reported health), which does not belong to the eight dimensions or the total SF-36 score. Each of these 8 dimensions has a score between 0 (worst health) to 100 (best health). [24-26]

Biochemical Assessment

Blood samples were collected early in the morning after 12-hour night-time fasting at the Nutrition and the Biochemistry Laboratory of the School of Nutritional Sciences Dietetics, TUMS. Samples of blood collected in parent tubes containing 0.1 EDTA, was taken following the standard protocol in a sitting position. Samples of serum were centrifuged for serum collection 10 min at 300 rpm, diluted in 1 ml tubes, and stored at −80 °C until the analysis. Tests were analyzed utilizing the Auto-Analyzer BT 1500 (Selectra 2; Vital Scientific, Spankeren, Netherlands). Hypersensitive serum C-reactive protein levels were measured by an immunoturbidimetric test with the Pars Azmoon kit (Pars Azmoon Inc. Tehran, Iran).

Anthropometric Assessment

Anthropometric measures, including body weight, body mass index, waist circumferences, and waist-hip ratio, were measured in an overnight fasting state, without shoes, with minimal clothing and by the use of a multi-frequency bioelectrical impedance analyzer In-body 770 scanner by trained dietitians (In-body Co., Seoul, Korea). Height was measured with a wall Seca 206 stadiometer (Hamburg, Germany), based on a standard protocol, their height was recorded to the nearest 0.2 cm.

Assessment of other Variables

Statistical Analyses

The normality of variables distribution was checked using the Kolmogorov-Smirnov test. We had no missing data.. EDII (as dichotomous) was examined across the following characteristics: age, weight, height, economic status, BMI, waist circumference, waist-hip ratio, energy intake, physical activity, and quality of life measurements, via independent sample T-test analyses. Comparisons of different food group intakes across the EDII categories were analyzed through an independent sample T-test. Multivariable linear regression analyses of the continuous EDII score were conducted to determine the association of the EDII with quality of life and hs-CRP levels. Variables were adjusted for the following confounding factors: age, weight, physical activity, smoking, economic status, and employment status. The results are reported as a percentage change (β) with 95% confidence intervals (95% CI). Statistical analysis was performed using SPSS version 21 (SPSS Inc., Chicago, USA). Significance was set at a probability of <0.05 for all tests.

Results
The dietary inflammatory potential scores in this study, as measured by EDII, ranged from -4.14 (most anti-inflammatory score) to 3.89 (most pro-inflammatory score). The mean (SD) age of the participants at recruitment was 36 (8). Table 1 presents participants’ characteristics in relation to different categories of dietary inflammatory indices. EDII was categorized into anti-inflammatory (EDII ≤ 0.05) and pro-inflammatory (EDII > 0.06) diets, based on the median value (0.05). When EDII was converted into two groups, significant differences were observed for IPAC mean 1162.45 (1322.88) (P<0.0001). The hs-CRP mean was level showed no significant change in the higher EDII score group compared to the other group (PC: 4.26±4.42% vs. 4.07±4.34%; P = 0.856).

**II ≤ 0.05: Anti-inflammatory diet, DII > 0.06: pro-inflammatory diet**

**Independent sample t-test was used for comparison of continuous variables between DII categories.**

Significant inverse differences were found between the three dimensions of SF-36, including physical functioning (P=0.033), mental health (P=0.021), and vitality (P=0.031), with anti-inflammatory and pro-inflammatory diet groups. For the other five dimensions, such as general health, role-physical, role emotional, social functioning, bodily pain, and health transition, decreasing trends were observed across EDII categories, but these relationships were not significant (Table 2).

Nutrients intake adjusted for energy intake before calculating EDII
EDII values were categorized according to the median.
(Anti-inflammatory diet: EDII ≤ 0.05, pro-inflammatory diet: EDII > 0.06)
Independent sample t-test was used for comparison of continuous quality of life measures between EDII categories.

Table 3 shows the distribution of 11 food groups: grains, refined grains, dairy products, beans, vegetables, fruits, red meat, processed meat, white meat, nut/olive group, and sweet/fat group across the EDII groups. The results showed that servings of vegetables and beans (P<0.0001) decreased significantly in the higher dietary inflammatory index group, whereas servings of sweet/fat group (P<0.0001) increased significantly in this group.

Data are presented as mean ± standard deviation. Nutrient intake was adjusted for energy intake before calculating EDII values were categorized according to the median.

Independent sample t test was used for comparison of food group's intake between EDII categories.

A direct association between EDII and physical functioning levels was observed after adjustment for potential confounders, such as age, weight, smoking, economic status, and employment status (P=0.024) (shown in Additional file 1: Table S1).

Multivariable linear regression analysis with adjustments for potential confounders demonstrated that EDII was significantly associated with mental health and vitality ($\beta = 5.58$, 95% CI 0.72, 10.43, $p = 0.024$, $\beta = 16.88$, 95% CI 10.75, 23, $p < 0.0001$ (shown in Additional file 2: Table S2) and $\beta = 14.29$, 95% CI 9.48, 20.36, $p < 0.0001$ (shown in Additional file 3: Table S3), respectively.

**Discussion**

It is important to note that this is the first study to examine the association between dietary inflammatory potential, quality of life, and inflammation levels among women. This cross-sectional study of Iranian women showed evidence of a positive association between higher EDII scores with a lower quality of life in certain measurements, such as physical functioning, mental health, and vitality. These findings emphasize the importance of addressing...
overall dietary quality in the future community- or population-based programs or policies to prevent chronic
disease.

Some prior research has shown that an inflammatory diet plays an important role in psychological health.
Amudena Sánchez-Villegas et al. also determined that a pro-inflammatory diet was associated with a significantly
higher risk of depression in a Mediterranean population, particularly in older subjects [29]. Tasnime N. Akbaraly et
al. found that a pro-inflammatory diet was associated with recurrent depression in women, which seems not to be
driven by circulating inflammatory markers [30]. There is considerable evidence that has suggested a better quality
of diet or an anti-inflammatory diet is associated with a better quality of life and mental health. Ujué Fresán et al.
have found that a Mediterranean diet was associated with reduced depression risks [31]. The current findings are
supported by an Australian study which reported that adherence to an MD pattern and better dietary quality is
associated with better mental health and wellbeing [32, 33]. A possible mechanism seems to be related to the fact
that an anti-inflammatory diet is rich in nutrients such as vitamins, minerals, antioxidants, and fiber, which have
beneficial health effects that have been widely demonstrated.

The results revealed no relationship between EDII and hs-CRP levels in women. To the best of the researchers’
knowledge, previous studies of dietary inflammatory indices and serum hs-CRP levels are generally consistent with
the findings of the present study. Several other studies have suggested that a pro-inflammatory diet is associated
with higher levels of inflammatory markers. Previous studies have shown that DII was associated with an increase
in the odds of elevated hs-CRP levels (.3 mg/l) [34]. Another study in the USA demonstrated that higher DII scores
were associated with inflammatory biomarkers including IL-6, TNF-α, and hs-CRP [35]. In the Asklepios study, no
significant associations were observed between DII and CRP and fibrinogen, but significant positive associations
between DII and IL-6 and homocysteine were observed [36]. Utilizing DII is one of the strengths of the present
investigation. DII found Overall diet, rather than individual foods and nutrients.

Conclusion

The most interesting finding of this study is that more anti-inflammatory diets are significantly associated with
higher physical function, mental health, and vitality in overweight and obese women. Thus, encouraging the intake
of more anti-inflammatory dietary factors, such as plant-based foods rich in fiber and phytochemicals, and
reducing intake of pro-inflammatory factors, such as fried foods or processed foods rich in saturated fat, maybe a
beneficial strategy for better physical and mental health.

Limitations

The present study had some limitations that should be considered. First of all, the use of self-reported FFQ is
known to contain a certain degree of measurement error, which might affect results. Moreover, an FFQ consisting
of 29 instead of 45 food parameters were used for calculating EDII. The small sample size is another
limitation, and data from larger sample size studies are more credible. Because our study population was 18-50
years old, overweight, and obese women, the relationship could not be generalizable to other populations of
different ages, genders, and backgrounds. Besides, since the research has a cross-sectional study, the causal
relationship between energy-adjusted dietary inflammatory index, inflammatory markers, and quality of life cannot
be inferred using retrospective observational studies; conducting prospective studies is thus highly recommended.

BMI: Body mass index; CVD: Cardiovascular disease; CRP: C-reactive protein; EDII: Energy-Adjusted dietary inflammatory index; ELISA: Enzyme-linked immunosorbent assay; FFQ: Food frequency questionnaire; HQOL: Health quality of life; HTN: Hypertension; Hs-CRP: High-sensitivity C-reactive protein; IL-6: Interleukin-6; IPAQ: International Physical Activity Questionnaires; MUFA: monounsaturated fatty acids; METs: Metabolic Equivalent Tasks; PUFA: Polyunsaturated fatty acids; QOL: Quality of life; SFA: Saturated fatty acids; T2DM: Type 2 diabetes mellitus; TNFα: Tumor necrosis factor-α; WHO: World Health Organization.

Declarations

Ethics approval and consent to participate

The study protocol has been approved by the ethics committee of Endocrinology and Metabolism Research Center of Tehran University of Medical Sciences (TUMS) with the following identification: IR.TUMS.VCR.REC.1395.1597. Each participant was completely informed about the study protocol and provided a written and informed consent form before taking part in the study. This study was approved by the research council (research project number: 95-03-161-33142).

Consent for publication

Each participant was completely informed about the study protocol and provided a written and informed consent form before taking part in the study.

Availability of data and materials

The data that support the findings of this study are available from Khadijeh Mirzaei but restrictions apply to the availability of these data, which were used under license for the current study, and so are not publicly available. Data are however available from the authors upon reasonable request and with permission of Khadijeh Mirzaei.

Competing interests

The authors declare that they have no competing interests.

Funding

This study was supported by grants from the Tehran University of Medical Sciences, Tehran, Iran (Grant number: 95-03-161-33142, 95-04-161-33893).

Authors’ contributions

The project was designed and implemented by NGh and KhM. Data were analyzed and interpreted NGH, HA, AM, SY, SAK, FSH, and HI prepared the manuscript. KhM, supervised the overall project. All authors read and approved the final manuscript.

Acknowledgments

We thank the School of Public Health, Tehran University of Medical Sciences and we would like to thank all the participants for their cooperation.
