Abstract

BACKGROUND *Klebsiella* species are among the most common causes of bloodstream infection (BSI). However, few studies have evaluated their epidemiology in non-selected populations. The objective was to define the incidence of, risk factors for, and outcomes from *Klebsiella* species BSI among residents of the western interior of British Columbia, Canada.

METHODS Population-based surveillance was conducted between April 1, 2010 and March 31, 2017.

RESULTS 151 episodes were identified for an incidence of 12.1 per 100,000 per year; the incidences of *K. pneumoniae* and *K. oxytoca* were 9.1 and 2.9 per 100,000 per year, respectively. Overall 24 (16%) were hospital-onset, 90 (60%) were healthcare-associated, and 37 (25%) were community-associated. The median patient age was 71.4 (interquartile range, 58.8-80.9) years and 88 (58%) cases were males. Episodes were uncommon among patients aged ≤ 40 years old and no cases were observed among those aged ≤ 10 years. A number of co-morbid medical illnesses were identified as significant risks and included (incidence rate ratio; 95% confidence interval) cerebrovascular accident (5.9; 3.3-9.9), renal disease 4.3; 2.5-7.0), cancer (3.8; 2.6-5.5), congestive heart failure (3.5; 1.6-6.6), **dementia** (2.9; 1.5-5.2), diabetes mellitus (2.6; 1.7-3.9), and chronic obstructive pulmonary disease (2.3; 1.5-3.5). Of the 141 (93%) patients admitted to hospital, the median hospital length stay was 8 days (interquartile range, 4-17). The in-hospital and 30-day all cause case-fatality rates were 24/141 (17%) and 27/151 (18%), respectively.

CONCLUSIONS *Klebsiella* species BSI is associated with a significant burden of illness particularly among those with chronic co-morbid illnesses.

Background

The *Klebsiella* genus, which including the species *K. pneumoniae* (including subspecies *pneumoniae* and *ozonae*), *K. oxytoca*, and *K. variicola* are important human pathogens. *Klebsiella pneumoniae* is second to *Escherichia coli* as the most frequent cause of Gram-negative bloodstream infections (BSI) in both hospital and community settings [1]. *Klebsiella pneumoniae* is an important cause of pneumonia, urinary tract infections, septicemia, and intra-abdominal infections [2, 3]. *Klebsiella pneumoniae* has become increasingly important in recent years, as invasive hypermucoid strains have been linked to pyogenic liver abscesses most notably in Taiwan and Korea [4, 5], and there has been an upswing in extended spectrum- β -lactamase (ESBL) producing strains worldwide [6-8]. Species other than *K. pneumoniae* are overall less frequent and have been associated with conditions including BSIs, urinary tract infections, soft tissue infections, and respiratory tract infections [9-11].

Population-based studies minimize a number of important biases and have been recognized as optimal designs to evaluate the epidemiology of BSIs [12]. However, to our knowledge only three previous studies have evaluated *Klebsiella species* BSI in non-selected populations [1, 13, 14]. Furthermore, only one of these has quantified the risks for development of *Klebsiella species* BSI related to specific co-morbid

illnesses [1]. The objective of this study was to determine the incidence and risk factors for acquiring *Klebsiella* BSI among residents of a non-selected Canadian population.

Methods

Study population & surveillance

Population surveillance was conducted in the western interior region of British Columbia, Canada (2016 population 182,422) as previously described [15]. All residents in the selected area with *Klebsiella species* BSI were identified by the regional microbiology laboratory at the Royal Inland Hospital in Kamloops and clinical information was obtained through case-by-case chart review. Comorbid illnesses were classified according to the method of Charlson [16]. The Interior Health Research Ethics Board approved this study and granted a waiver of individual informed consent (file 201314052-I).

Laboratory procedures and definitions

All blood was cultured using the BacT/Alert 3D System (bioMerieux, France). A blood culture set consisted of an aerobic/anaerobic bottle pair obtained from a single draw. Standard practice was to draw two sets of blood cultures from different sites. Organisms were isolated and speciated by examining lactose-fermenting mucoid colonies on Mac plates. Oxidase tests and MALDI-TOF were then used, along with Gram stain results, for species identification. For the purposes of this study, *K. pneumoniae* included those identified as *K. pneumoniae* and *K. pneumoniae subspecies pneumoniae* or *ozonae*.

An incident *Klebsiella species* BSI was defined by the growth from at least one blood culture set. Repeat isolations of the same species in a given patient within 30 days were considered to represent the same episode and repeat isolations within 30-365 days were classified as new incident infections only if the initial episode was treated with clinical resolution. Isolates were reviewed case-by-case to exclude contaminants and establish clinical significance as determined by detailed microbiology, radiologic, and clinical information review. Community-onset and hospital-onset BSI were those where the index positive blood culture was drawn within 48 hours or more after admission to an acute care hospital, respectively [17]. Community-onset BSIs were further classified as either healthcare-associated or community-associated using the definitions of Freidman *et al* [18].

Statistical analysis

All analyses were performed using Stata version 15 (Stata Corp, College Station, TX). Differences in proportions among categorical data were assessed using Fisher's exact test. Medians with inter-quartile range (IQR) were used to describe skewed continuously distributed variables. Incidence rates were calculated using regional census data [19]. Risks were calculated and reported as incidence rate ratios (IRR) with 95% confidence intervals (CI). A number of co-morbid illnesses were assessed as risk factors for the development of *Klebsiella species* BSI. Denominator data was obtained from local sources [20, 21], provincial and national surveys [22-28], and studies published elsewhere [29].

Results

Incidence

During the seven years of surveillance, 153 incident BSI isolates of *Klebsiella species* were identified. In two cases infections had two different incident *Klebsiella species* concomitantly isolated and these included one patient with *K. oxytoca* and *K. pneumoniae* and another with *K. oxytoca* and *K. variicola* co-infection. There were therefore 151 incident *Klebsiella species* BSI episodes among 139 regional residents for an overall annual incidence rate of 12.1 per 100,000 per year. The incidence of *K. pneumoniae* and *K. oxytoca* were 9.1 and 2.9 per 100,000 per year, respectively. The remaining two incident isolates were *K. variicola*. Eleven patients had a second and one patient had a third episode of *Klebsiella species* BSI during the surveillance period. Twenty-four cases (16%) were hospital-onset, 90 (60%) were healthcare associated, and 37 (25%) were community-associated.

The annual incidence varied during the study years as shown in Figure 1. The first five years of the study demonstrated moderate year-to-year variability ranging from 6.8 to 11.7 per 100,000 annually but there was then a marked increase during the fifth and six years of the study (Figure 1). Although both species increased in incidence in the latter years of the study this was predominantly related to *K. pneumoniae* BSI in the last study year.

Risk factors and predisposing conditions

The median patient age was 71.4 (IQR, 58.8-80.9) years and 88 (58%) were male. No cases were observed among those aged less than 10 years and the incidence increased with older age as shown in Figure 2. Males were at higher risk but this was not statistically significant (14.0 vs. 10.1 per 100,000; IRR, 1.4; 95% CI, 1.0-1.9; p=0.06).

The median Charlson co-morbidity score was 2 (interquartile range, 1-4). Twenty-eight (19%) patients had a Charlson score of zero, and sixty-two (41%) had scores of 1-2, thirty-two (21%) 3-4, and twenty-nine (19%) had five or more. A number of co-morbidities were examined as risks for development of a *Klebsiella species* BSI within the population and these are shown in Table 1.

Clinical foci and microbiology

The most common focus of infection was intra-abdominal or genitourinary as shown in Table 2. Although *K. pneumoniae* was much more likely to be of hospital-onset as compared with *K. oxytoca* BSI (23/113; 20% vs. 1/35; 3%; relative risk 7.1; 95% confidence interval 1.0-50.9; p=0.016), otherwise the demographics and clinical features were similar (Table 2). Although there was a high rate of resistance to ampicillin, most isolates overall were susceptible to ceftriaxone, ciprofloxacin, gentamicin, and co-trimoxazole (Table 2). As compared to *K. pneumoniae*, *K. oxytoca* had a significantly reduced rate of susceptibility to cefazolin (Table 2).

Hospital admission and outcome

One hundred and forty-one (93%) patients were admitted to hospital for a median hospital length stay of 8 (IQR, 4-17) days. The in-hospital and 30-day all cause case-fatality rates were 24/141 (17%) and 27/151 (18%), respectively. The 30-day all cause case-fatality rates were 20% (23/113) and 9% (3/35; $p=0.1$) for *K. pneumoniae* and *K. oxytoca*, respectively.

Discussion

In this study, we observed that *Klebsiella species* are frequent causes of BSI. The incidence rate of *Klebsiella species* BSI was 12.0/100,000, and a number of co-morbid medical conditions were associated with significantly increased risk. Furthermore, one in five patients suffering from *Klebsiella* BSI died within 30 days of diagnosis. *Klebsiella species* BSI cause a significant burden of illness in our population.

To our knowledge, there are only three previous population-based studies published for comparison [1, 13, 14]. Meatherall *et al* reported on 640 episodes in the Calgary area of Canada during the years 2000 to 2007 and found an incidence rate of for *K. pneumoniae* of 7.1/100,000 [1]. Pepin reported an incidence of 18.7/100,000 in Sherbrooke, Canada, between the years 1997 and 2007, with 411 episodes identified in that time [14]. Finally, Al-Hasan reported 127 episodes in Olmsted County, Minnesota, between the years 1998 and 2007, with an annual incidence rate of 11.7/100,000 for *Klebsiella species* BSI, and 9.7/100,000 for *K. pneumoniae* specifically [13]. The cumulative data from North American population-based studies to date indicate that the incidence rate for *Klebsiella species* BSI is comparable to our observed rate of 12 per 100,000. Individual differences between studies may potentially be explained in part by differences in demographics, rates of culturing, and distribution of risk factors in these populations.

A number of studies have identified co-morbidities most notably cancer and diabetes as risk factors for development of *Klebsiella species* BSI [1, 14, 30-34]. However, with the exception of the population-based investigation reported by Meatherall *et al*, these studies have been within selected cohorts that are at significant potential risk for bias. In their study from Calgary, Meatherall *et al* found a number of determinants and that solid organ transplantation, chronic liver disease, dialysis, and cancer were the most important risk factors for development of *K. pneumoniae* BSI [1]. We also observed that renal disease and cancer were significant risk factors for *Klebsiella species* BSI but notably we did not find that liver disease significantly increased the risk. While diabetes was found to be a significant risk factor in both of our studies, after considering the high prevalence among controls in the population the magnitude of this risk was relatively low compared to other co-morbidities (Table 2). There are many reasons why observed risk factors may be different in populations and may be related to the specific populations under evaluation and the differences in study methodologies and definitions.

While this study benefits from the population-based design there are some limitations that merit discussion. First, it is possible that we could have failed to ascertain cases that occurred among residents of our region seeking health care outside our region. Given that almost all tertiary services are available in our area, we suspect that this represents a small number but do not have actual empiric data to justify this claim. Second, a diagnosis of a BSI requires a positive blood culture and as such is related to the decision of clinicians to draw a specimen for testing. This is a limitation inherent to all BSI studies. Third, in

establishing comorbid illnesses we did not have individual patient level data on co-morbid illnesses on residents of the region that did not develop BSI and therefore had to estimate prevalence rates in our calculations. A degree of imprecision therefore exists in our determinations and the magnitude of the risk factors reported should be interpreted accordingly. Finally, because of the lack of individual co-morbidity data on controls we were not able to determine independent risk factors for acquisition.

Conclusion

In summary, our study documents the major burden of *Klebsiella species* BSI in our region and is a significant addition to the small number of previous population-based studies conducted in other areas in Canada and the United States. We further identify and confirm that a number of co-morbidities are risk factors for these infections. Further population-based studies conducted in other regions outside of North American are warranted.

List Of Abbreviations

BSI: Bloodstream Infection

CHHF: Congestive heart failure

CI: Confidence Interval

COPD: Chronic Obstructive Pulmonary Disease

CVA: Cerebrovascular accident

ESBL: Extended Spectrum-Beta-Lactamase

IQR: Inter-Quartile Range

IRR: Incidence-Rate Ratio

MALDI-TOF: Matrix Assisted Laser Desorption/Ionization – Time Of Flight

MI: Myocardial Infarction

PVD: Peripheral vascular disease

RIH: Royal Inland Hospital
