25   **ABSTRACT**

26   The focus of this paper is directed towards investigating the influence of multiple freeze-thaw

27   (FT) cycles on the stress-strain relationships during undrained shearing for an expansive soil

28   under a wide range of confining stresses (σ_c) from 0 to 300 kPa. Different numbers of FT

29   cycles were applied to compacted specimens. The influence of FT cycles on the soil's

30   structure was investigated using mercury intrusion porosimetry (MIP) and scanning electron

31   microscope (SEM) tests. FT impacted specimens were subjected to consolidated undrained

32   (CU) shear tests with pore pressure measurement (σ_c = 10 to 300 kPa) and unconfined

33   compression (UC) tests (σ_c = 0 kPa) to derive the shearing stress-strain relationships and the

34   associated mechanical properties including (i) failure strength (q_u), elastic modulus (E_u),

35   effective and apparent cohesion (*c'* and *c*), and effective and apparent friction angle (ϕ' and ϕ)

36   obtained from CU tests and (ii) q_u and reloading modulus ($E_{1\%}$) and stress ($S_{u1\%}$) at 1% strain

37   obtained from UC tests. Testing results show that FT cycles mainly influence the soil's

38   macropores with diameters between 5 and 250 microns. Cracks develop during FT cycles and

39   result in slight swelling which contributes to an increase in the global volume of the soil

40   specimens. There is a significant reduction in the investigated mechanical properties after FT

41   cycles. They typically achieve equilibrium after about 6 cycles. The shearing stress-strain

42   curves transits from strain-softening to strain-hardening as the confining stress increases. An

43   empirical model is developed to describe the strain-softening behavior of the specimens

44   under low confining stresses. The model is simple to use and well describes all stress-strain

45   curves obtained in this study that show strain-softening characteristics.

46

47   **Keywords:** Expansive soil; Freeze-thaw; Microstructure; Volumetric change; Shear behavior.

48 **Highlights:**

49 • FT cycles destruct macropores and contribute to micro- and macrocracks

50 • The strength degradation associated with microstructural changes is explained

51 • The strain-softening behaviors under low stress levels of FT cycles are modeled

1 INTRODUCTION

Expansive soils are typically referred to as problematic soils by geotechnical engineers because of their significant swelling and shrinkage characteristics associated with variations in their water content (Li et al. 1992; Nelson and Miller 1992; Zou et al. 2018). These soils are widely distributed in many countries in the world, which include India, Israel, Canada, Australia, China, and the USA (Jones and Holtz 1973; Ramana, 1993). The complex variations in their engineering properties have a significant influence that results in damages to the geotechnical infrastructures constructed on or adjacent to them. Expansive soils typically lead to non-uniform settlement of structures, cracking of walls and pavements, and landslides of expansive soil slope (Holtz and Gibbs 1956; Aitchison et al. 1973; Alonso et al. 1987; Chen, 1988; Schick et al. 1999; Miao et al. 2002; Tripathy et al. 2002; Glade, 2005; Ajdari et al. 2013; Zhang et al. 2015; Massat et al. 2016; Zou et al. 2020). According to a recent study by Adem and Vanapalli (2013), the economic losses caused by expansive soils were estimated to be approximately several billion dollars in many countries in recent years.

There is a rapid development of geotechnical infrastructure in expansive soils regions in China that are typically subjected to numerous freeze-thaw cycles annually (Lai et al. 2012; Kong et al. 2018; Tang et al. 2018). A new large-scale water conveyance canal constructed in Northeast China, which is 203 km in length, is an example of such an infrastructure in typical weak and medium expansive soils (Xu et al. 2016). The expansive soils in this region are subjected to periodic freeze-thaw (FT) cycles with fluctuations in the ground temperature. Due to this reason, there is ice formation and the migration of water in the expansive soils (Edwin and Anthony 1979, Liu et al. 2016), resulting in a change in the density and the engineering properties, which include, coefficient of permeability, shear strength and volumetric change (Qi et al. 2008; Aldaood et al. 2014; 2016; Zhang et al. 2015; Liu et al.

4

77   2017). There is evidence to show that these changes have contributed to numerous landslides

78   in the water conveyance canal (Xu et al. 2016; Zhang et al. 2018).

79

80   Expansive soils contain high quantities of swelling clay minerals such as montmorillonite and

81   illite that have a significant influence on the volumetric variations during cyclical moisture

82   content changes (Alonso et al. 1999; Tripathy et al. 2002). The volume change is typically

83   characterized by significant expansion and weakening upon wetting and shrinkage and

84   cracking upon drying, which cause extensive damages to the adjacent infrastructure and even

85   result in natural disasters (Holtz and Gibbs 1956; Berndt and Coughlan 1976; Chen and Ma

86   1987; Chen 1988; Lin and Cerato 2013; Gatabin et al. 2016; Liu et al. 2020). A significant

87   number of studies focused on the effect of drying-wetting cycles on the structural, volumetric,

88   and hydro-mechanical behaviors of expansive soils (Grant 1974; Albrecht and Benson 2001;

89   Cui et al. 2002; Alonso et al. 2005; Cuisinier and Masrouri 2005; Pires et al. 2008;

90   Nowamooz and Masrouri 2008; Ajdari et al. 2013; Wang et al. 2017). Also, several studies

91   have investigated the influence of freeze-thaw cycles on the mechanical behavior of various

92   soils, such as saline soil (Han et al. 2018), loess (Li et al. 2018), dispersive soil (Han et al.

93   2021), silty soil (Cui et al. 2014; Chen et al. 2019) and mine tailings (Liu et al. 2018).

94   However, due to the expansive soils' complex deformation characteristics, the evolution of

95   engineering properties of expansive soils during FT cycles are more complex in comparison

96   to conventional soils. There are limited studies in the literature that address the effects of FT

97   cycles on the microstructure and mechanical behavior of expansive soils. In particular, the

98   effects of FT cycles on mechanical behaviors under low stress levels are not well understood.

99

100   In this study, the volumetric characteristics, the stress versus strain relationships, and shear

101   strength behaviors of an expansive soil collected from Northeastern China under the effects

102 of FT cycles were investigated. The investigated mechanical behaviors include (i) unconfined

103 compression strength and the unloading-reloading modulus, (ii) shear strength, elastic

104 modulus, and strength parameters (i.e. cohesion and internal friction angle) that were

105 obtained from consolidated undrained shear tests. Microstructural changes were derived from

106 mercury intrusion porosimetry (MIP) and scanning electron microscope (SEM) tests. Besides,

107 an empirical model is proposed to describe the strain-softening behavior of expansive soil

108 specimens under low confining pressures that can serve as a useful numerical tool.

109

110 **2 EXPERIMENTAL INVESTIGATIONS**

111 **2.1 Materials**

112 An expansive soil collected from Qiqihar, Heilongjiang, China is used for this research study.

113 The sampling site is a typical seasonally frozen region characterized by hot summer and cold

114 winter. The average temperature ranges from 23.1°C in summer to −18.6°C in winter. The

115 expansive soil was excavated from approximately 1m beneath the ground surface, and the

116 in-situ natural gravimetric water content (w_n) and dry density (ρ_{dn}) of the sampled soil was

117 26.3% and 15.09 kN/m^3, respectively. Physical index properties of the tested soil are

118 summarized in Table 1.

119

120 XRF tests were conducted to determine the chemical components of the soil. The major

121 chemical components and their contents by mass are SiO_2, 60.48%; Al_2O_3, 18.53%; Fe_2O_3,

122 6.63%; K_2O, 3.05%; CaO, 4%. XRD tests were conducted to reveal the mineral components

123 of the soil. The major minerals are Quartz, Illite, Albite, and Calcite. According to the

124 standard of GB 50112-2013 (Ministry of Housing and Urban-Rural Development, P.R. China,

125 2013) and the free swelling ratio of 67%, this soil is classified as moderately expansive soil.

126

2.2 Specimen preparation and application of FT cycles

127

128 The collected expansive soil samples were air-dried, pulverized with a rubber mallet, and

129 then passed through a 2mm sieve to remove gravels and large size particles. To simulate the

130 field condition, the air-dried soil was wetted with water such that the natural water content of

131 26.3% is achieved. The moist soil was statically compacted at the natural dry density of

132 1540kg/m^3 into cylindrical specimens (38mm in diameter and 76mm in height) for

133 microstructure investigations and triaxial tests. Compacted specimens were sealed in layers of

134 Saran wrap and stored in plastic containers for at least 72h at room temperature of 25±1°C to

135 ensure that water was evenly distributed within the specimens.

136

137 Specimens were subjected to freeze-thaw cycles in a closed-system condition. There is

138 limited or no moisture migration during freezing and thawing processes because of the

139 relatively low coefficient permeability of expansive soils, especially under unsaturated and

140 frozen conditions (Chamberlain 1973; Yarbasi et al. 2007; Lu et al. 2018). A temperature

141 chamber with a precision of ±0.05°C and a temperature range from 100°C to -40°C was used

142 to apply FT cycles.

143

144 During FT cycles, all specimens remain wrapped in Saran sheets and stored in plastic

145 containers which were firstly frozen at −20°C for at least 12h and then allowed to thaw at

146 20°C for another 12h. The temperature range was chosen following the local annual

147 temperature variation (i.e. −18.6°C to 23.1°C). A 12h period is considered enough for

148 achieving equilibrium conditions as small-size specimens are used in this study (Lu et al.

149 2019; Ding et al. 2020). Such freezing and thawing procedure was repeated until the

7

150   designated number of FT cycles (i.e. N_{FT} = 0, 1, 4, 6, 10) was reached.

151

152   **2.3 Measurement of volumetric change**

153   To study the volumetric behavior of expansive soil specimens during FT cycles, the volume

154   measurements were performed on specimens after each freezing and thawing process. An

155   electronic Vernier caliper with an accuracy of 0.005mm was used to directly measure the

156   diameter and height of the specimens. Preliminary studies have shown that the volumetric

157   strain (ε_v) during FT cycles was found to be uniform in the homogenous soil specimens

158   which is consistent with the assumption of the uniform distribution of water phase in soil

159   mass and is widely used by various researchers (Zeng et al. 2018; Lu et al. 2019). Thus,

160   diameter (i.e. d_1, d_2, and d_3) and height (i.e. h_1, h_2, and h_3) measurements were taken at three

161   different cross-sections that are evenly distributed on the surface of the specimens. The

162   average values of diameter and height measurements were used to calculate the global

163   volume of the specimens and the void ratio (e) or volumetric strain (ε_v) – water content (w)

164   relationships.

165

166   **2.4 MIP and SEM tests**

167   To track the evolution of the microstructure of specimens upon freeze-thaw cycles, the

168   mercury intrusion porosimetry (MIP) tests and scanning electron microscopy (SEM) tests

169   were performed on untreated specimens and specimens subjected to 1, 4, 6, and 10 FT cycles.

170   MIP tests determine quantitatively the distribution and size of soil's pores while SEM tests

171   capture the cross-section morphology of the microstructure.

172

173   Approximately 2g of mass trimmed from test specimens subjected to different FT cycles were

174   collected for use in MIP and SEM tests. They were freeze-dried in liquid nitrogen to preserve

175   the soil structure and remove the pore water before testing. The trimmed specimens were then

176   subjected to MIP tests in a PoreMaster 33 porosimeter and SEM tests in an FEI Quanta 200

177   SEM testing system.

178

179   **2.5 Determination of mechanical properties**

180   A GDS static triaxial testing system (manufactured by GDS Instruments Ltd., Hampshire,

181   U.K., as shown in Figure 1), was utilized for the consolidated undrained (CU) triaxial

182   compression tests and unconfined compression (UC) tests to determine the mechanical

183   properties of expansive soil subjected to FT cycles. It should be noted that the UC tests were

184   performed on both saturated (specimens after achieving designed FT cycles were saturated

185   before performing the tests) and unsaturated specimens (specimens after achieving designed

186   FT cycles were directly used for tests), while CU tests were only performed on saturated

187   specimens.

188

189   Before performing the CU triaxial compression tests, the untreated specimens were subjected

190   to planned FT cycles and were vacuum saturated over a period of 24h. They were thereafter

191   transferred to the triaxial chamber where they were further subjected to back-pressure

192   saturated until the pore-water pressure parameter, B exceeds 0.90 (Kamruzzaman et al. 2009).

193   Afterward, the specimens were consolidated under seven different confining pressures (σ_c) of

194   10, 20, 30, 50, 100, 200, 300kPa. The consolidation process was assumed to have been

195   completed when the specimens' volumetric changes leveled off and their excess pore water

9

196 pressure has dissipated. Finally, the specimens were sheared under undrained conditions at a

197 shear strain rate of 0.066%/min until the axial strain reached 20%.

198

199 The unconfined compression (UC) tests following the methodology suggested by Han and

200 Vanapalli (2017). This methodology involves an unloading-reloading loop starting at 1%

201 axial strain (ε_a) to determine the axial stress at ε_a =1% before the unloading process (i.e. $S_{u1\%}$)

202 and the reloading modulus at ε_a =1% (i.e. $E_{1\%}$). The unconfined compression strength (q_u)

203 was determined after the specimens were loaded to failure. A loading and unloading rate of

204 1mm/min was adopted following the ASTM D2166-13 (2013) protocol. The $S_{u1\%}$ and $E_{1\%}$ are

205 elastic properties and q_u indicates the unconfined shear strength of the specimens (Lee et al.

206 1997; Lu and Kaya 2013). Detailed discussions of the use of $E_{1\%}$, $S_{u1\%}$, and q_u and testing

207 procedures of the revised UC tests are available in Lee et al. (1997) and Han and Vanapalli

208 (2017). Figure 2 shows the schematic diagram of the stress-strain relationship during the

209 revised UC tests and the determination of the $E_{1\%}$, $S_{u1\%}$, and q_u.

210

211 **3 TESTS RESULTS AND DISCUSSIONS**

212 **3.1 Volumetric characteristics**

213 The volumetric strain (ε_v) of specimens during FT cycles can be defined using Eq. 1.

214
$$\varepsilon_v = \left(V_N - V_0\right)/V_0 \times 100\%$$
(1)

215 where V_0 is the initial volume of the untreated specimen, V_N is the volume of the specimen

216 after experiencing N FT cycles. Positive ε_v indicates swelling while negative ε_v refers to

217 shrinkage.

218

219   The evolution of ε_v during 1, 4, 6, 10 FT cycles is shown in Figure 3. The volume change of

220   specimens with different N_{FT} shows similar features (i) there is an increase in the ε_v (i.e.

221   expansion) during the freezing process and (ii) there is a decrease in the ε_v (i.e. shrinkage)

222   during the thawing process. The ε_v during initial several FT cycles are significant but its scale

223   reduces gradually with an increase in the N_{FT}. The volumetric deformation behavior is elastic

224   after about 4 FT cycles, meaning that the non-recoverable ε_v becomes almost negligible when

225    $N_{FT} \geq 4$, which is consistent with the observations of other similar studies reported in the

226   literature (Viklander 1998; Wang et al., 2017; Zeng et al., 2018). FT cycles result in a slight

227   expansion of ε_v (ε_v = 1.2%) in the specimens' volume after 10 FT cycles.

228

229   **3.2 Evolution of soils' microstructure**

230   The MIP test results of specimens subjected to different FT cycles (N_{FT} = 0, 1, 4, 6, 10) are

231   plotted in Figure 4. Related SEM images are shown in Figure 5. MIP results are presented in

232   the form of (i) cumulative intrusion (CI) curves (Figure 4a) and (ii) pore size distribution

233   (PSD) curves (Figure 4b). The CI curves are defined as the relationship between the intruded

234   mercury void ratio, e_{MIP} (e_{MIP} = V_m / V_s where V_m is the volume of intruded mercury and V_s is

235   the volume of the soil solids), and the pore diameter, d. The PSD curves are the derivatives of

236   CI curves (i.e. $-\delta e_{MIP}/\delta \log d$ versus $\log d$ relationships).

237

238   It is observed from Figure 4b that untreated specimens (N_{FT} = 0) have a bimodal PSD curve

239   and with two dominant peaks: the peak of micro-pores at about 1.3μm and the peak of

240   macro-pores at about 30μm. This observation is consistent with the previous studies that the

241   as-compacted specimens usually show bimodal PSD curves (Wang et al, 2014; Burton et al,

242   2015). Macropores with diameters close to 30μm also can be observed in SEM images (see

243   Figure 5).

244

245   For a better description of the microstructure's evolution during FT histories, the CI and PSD

246   curves were separated into three zones (i.e. zones A, B, and C) by two boundaries which are

247   defined at 0.1μm and 5μm (see Figure 4). 0.1μm is chosen because all PSD curves converge

248   at the left of this threshold suggesting that these pores with diameters smaller than 0.1μm are

249   hard to be affected during FT cycles. 5μm is chosen as the delimiting boundary separating the

250   macro-pores and micro-pores in PSD curves of the tested soil, which is consistent with the

251   criterion proposed by Burton et al. (2015). 5μm is the turning point of PSD and CI curves

252   which refer to the beginning of the main population of micro-pores.

253

254   In order to quantitatively evaluate the variation of microstructures, the void ratio in zones A,

255   B, and C (denoted as $\Delta e_{MIP,A}$, $\Delta e_{MIP,B}$, $\Delta e_{MIP,C}$) are calculated by $e_{MIP,A} = e_{MIP,0.01} - e_{MIP,0.1}$,

256    $e_{MIP,B} = e_{MIP,0.1} - e_{MIP,5}$, $e_{MIP,C} = e_{MIP,5}$ where $e_{MIP,N}$ is the e_{MIP} value at Nμm. The $e_{MIP,0.01}$ is the

257   total void ratio intruded by mercury in the MIP tests ($e_{MIP,0.01} = \Delta e_{MIP,A} + \Delta e_{MIP,B} + \Delta e_{MIP,C}$).

258   The values of $\Delta e_{MIP,A}$, $\Delta e_{MIP,B}$, $\Delta e_{MIP,C}$ and $e_{MIP,0.01}$ are summarized in Table 2.

259

260   The following information can be derived from Figures 4 and 5 and Table 2:

261   (i)   In Zone A, the FT cycles have a negligible effect on the microstructure as the shape of

262   CI and PSD curves remain unchanged and the calculated void ratio in this zone (i.e.

263           $e_{MIP,A}$) is approximately the same after different FT cycles.

264   (ii)   In Zone B, the $e_{MIP,B}$ decreases during FT cycles, such behavior suggests that some

265   micro-pores transformed into macro-pores due to the ice crystal formation during the

266   process of freezing. This is the result of irreversible frost-induced plastic deformation

267   of soil particles in the subsequent thawing process. The peak of the micro-pores in the

268   PSD curve shifts to the right, indicating a slight increase in the diameter of the

269   dominant micro-pores. The frequency (i.e. $-\delta e_{MIP}/\delta \log d$) corresponding to the peak of

270   the PSD curve, also decreases after FT cycles.

271   (iii) In Zone C, the $e_{MIP,C}$ increases during FT cycles, which confirms the transformation of

272   micro-pores to macro-pores. The peak of compaction-induced macro-pores in the PSD

273   curve of the initial untreated specimen disappears after a few FT cycles. However, a

274   new plateau in the range of 5-20μm develops which is stable during FT cycles. This

275   behavior also suggests that the compaction-induced macro-pores are unstable and prone

276   to collapse upon FT processes.

277   (iv) The evolution of microstructures during FT cycles observed in MIP results is consistent

278   with the SEM images. As shown in Figure 5, the variation of pores' size and the

279   development of cracks induced by FT cycles can be easily observed. The cracks

280   induced by FT cycles segregate the soil particles and ultimately lead to a fragmented

281   soil structure.

282

283   **3.3 Unconfined compressive strength properties**

284   Figure 6 shows the stress-strain curves (i.e. axial stress, σ_1 versus axial strain, ε_1) obtained

285   from unconfined compression tests on saturated and unsaturated specimens with different FT

286   cycles (N_{FT} = 0, 1, 4, 6, 10). The σ_1-ε_1 relationships show strain-softening characteristics.

287   With an increase in the FT cycles, axial strain at the peak strength (denoted as ε_p) increases

288   from approximately 2% of the untreated specimen to 3% after 10 FT cycles, for both

289   saturated and unsaturated specimens, and the pre-peak stress-strain curves tend to become flat.

290   The stress-strain curves of specimens with different N_{FT} seem to have an identical residual

291   strength of approximately 15 and 30kPa for saturated and unsaturated specimens, respectively.

292   Comparing Figure 6(a) and (b), it can be observed that the saturated specimens have lower

293   residual strength and much lower peak strength than the unsaturated specimens, despite the

13

294   consistent trends in stress-strain curves.

295

296   The evolution of q_u, $E_{1\%}$, and $S_{u1\%}$ values with N_{FT} is shown in Figure 7. A power function

297   (Eq. 1) is used to describe the variation of q_u, $E_{1\%}$, and $S_{u1\%}$ with N_{FT} under unconfined

298   compression.

$$\frac{\Omega_N}{\Omega_0} = \frac{1+\alpha e^{-\beta N}}{1+\alpha} \tag{1}$$

299

300   where Ω_0 collectively represents the q_u, $E_{1\%}$, and $S_{u1\%}$ of untreated specimens, Ω_N is the q_u,

301    $E_{1\%}$, and $S_{u1\%}$ after N cycles of treatment, α and β are model parameters, $e = 2.7182$. The

302   fitting curves are shown in Figure 7 and the values of fitting parameters (i.e. α, and β) are

303   summarized in Table 3. The variation in the q_u, $E_{1\%}$, and $S_{u1\%}$ with N_{FT} is well described by

304   the proposed power function with $R^2 > 0.9$. The following information can be derived from

305   Figure 7 and Table 3:

306   (i)   The q_u, $E_{1\%}$, and $S_{u1\%}$ decrease with increasing N_{FT}, especially during the initial two FT

307   cycles ($N_{FT} = 1, 4$), which is followed by a slow decrease with further FT cycles and

308   reach equilibrium for unsaturated tests of approximately $N_{FT} = 6$ and saturated tests of

309          $N_{FT} = 4$, respectively.

310   (ii) The values of q_u, $E_{1\%}$, and $S_{u1\%}$ obtained from saturated specimens are much lower than

311   the ones of unsaturated specimens under the same N_{FT}. For example, the q_u, $E_{1\%}$, and $S_{u1\%}$

312   of saturated specimens decrease by 49.1%, 54.0%, and 71.4% from the initial values of

313   55kPa, 8.45MPa, and 49kPa for untreated specimens to 28kPa, 3.89MPa, and 14kPa after

314   10 FT cycles, respectively. For unsaturated specimens, the q_u, $E_{1\%}$, and $S_{u1\%}$ decrease

315   only by 46.0%, 45.2%, and 56.7% from 113kPa, 15.65MPa and 97kPa to 61kPa,

316   8.57MPa, and 42kPa, respectively. Thus, the decrease in the mechanical properties is

317   more significant during FT cycles when the moisture content is higher.

3.4 Shear strength and elastic modulus during consolidated undrained shearing

CU tests were conducted on specimens under seven confining stress levels (σ_c =10, 20, 30, 50, 100, 200, 300kPa) and with different N_{FT} (N_{FT} = 0, 1, 4, 6, 10) for comprehensive evaluation of the influence of FT cycles on the mechanical properties of expansive soil.

The stress-strain relationships (i.e. deviator stress q versus axial strain ε_1; $q = \sigma_1 - \sigma_c$) obtained from consolidated undrained triaxial shear tests under various confining pressures of the specimens subjected to FT cycles shown in Figure 8. The untreated specimens and the specimens subjected to FT cycles exhibit strain-softening behavior (see Figure 8) under low confining pressures (i.e. 10, 20, and 30kPa). However, the strain-softening behavior gradually decreases with increasing confining pressure. The stress-strain curves start to show a strain-stabilization behavior when the confining pressure exceeds 50kPa and show a strain-hardening behavior at a confining pressure of 100 and 300kPa (see Figure 8). The shear strength (i.e. q_u) is equal to the peak deviator stress for the specimens exhibiting strain-softening characteristics. However, the shear strength is estimated at the axial strain of 15% for the specimens exhibiting strain stabilization or hardening characteristics (Zhang et al. 2015; Liu et al. 2018). Typical results of the failure strength due to FT cycles under low and high confining pressures are given in Figure 9.

The shear strength (i.e. q_u) for all specimens decreases with an increase in the N_{FT} and reaches an equilibrium after approximately 6 cycles regardless of the confining pressure (i.e. σ_3). A more significant reduction however was observed for low confining stress (i.e. $\sigma_c = 10$, 20, and 30kPa). According to Wang et al. (2007) and Tang et al. (2018), a more compacted structure is formed due to the soil particle rearrangement associated with the closure of cracks induced due to the influence FT cycles.

15

343

344   The elastic modulus (i.e. E_u) is an important parameter that reflects the ability of a soil to

345   resist deformation (Tang et al. 2018; Han et al. 2018). According to Lee et al. (1995), the

346   elastic modulus can be calculated using Eq. (2) from stress-strain curves:

347
$$E_u = \frac{\Delta q}{\Delta \varepsilon} = \frac{q_{1\%} - q_0}{\varepsilon_{1\%} - \varepsilon_0} \tag{2}$$

348   where Δq and $\Delta \varepsilon$ are the increments of deviator stress and axial strain, respectively; $q_{1\%}$ is the

349   deviator stress corresponding to an axial strain of 1% (i.e. $\varepsilon_{1\%}$), q_0 is the initial deviator stress

350   corresponding to initial axial strain ε_0. The results of E_u for specimens subjected to FT cycles

351   under various low and high confining pressures are given in Figure 10.

352

353   A significant reduction in the E_u with an increase in the N_{FT} can be observed. Such behavior

354   is due to the modified micro-structures introduced by freeze-thaw cycles, which greatly

355   reduce the ability of specimens to resist elastic deformation. These observations are

356   consistent with the variations of q_u that almost no appreciable decrease in the E_u was

357   observed after $N_{FT} = 6$.

358

359   The effective and apparent cohesion (c' and c, kPa) and the effective and apparent cohesion

360   internal fraction angle (ϕ' and ϕ, °) under each confining pressure was separately determined

361   from the Mohr-Coulomb model (Eq. 3) to evaluate their evolutions with N_{FT}.

362
$$\sigma_1 = \frac{2c \cos \phi}{1 - \sin \phi} + \frac{1 + \sin \phi}{1 - \sin \phi} \sigma_3 \tag{3a}$$

363
$$\sigma_1' = \frac{2c' \cos \phi'}{1 - \sin \phi'} + \frac{1 + \sin \phi'}{1 - \sin \phi'} \sigma_3' \tag{3b}$$

364   The evolution of determined c' and ϕ' and c and ϕ with different N_{FT} are summarized in

365   Figures 11 and 12, respectively.

16

366

Because of the particle rearrangement and compaction effects during the consolidation and

shearing processes, the effective and apparent cohesion (i.e. c' and c) and internal friction

angle (i.e. ϕ' and ϕ) exhibit a non-linear characteristic as the confining pressure increases. A

lower cohesion and higher internal friction angle were observed for lower confining pressures,

these results are consistent with the previous studies (Chen and Liu 1990; Jiang et al. 2003;

and Li and Cheng 2012). An obvious reduction was also observed in the shear strength

parameters c' and ϕ' with the increasing cycle number, N_{FT}. Such a behavior can be attributed

to the influence of FT cycles that introduce cracks to soil structure (see Figure 5), which

reduce the integrity of soil particles that results in a reduction of their effective contacts.

376

The aforementioned power function (Eq. 1) was also used to describe the variation of q_u, E_u,

c' and ϕ' and c and ϕ with different N_{FT} under consolidated undrained shearing. The fitting

curves are shown in Figures 9, 10, 11, and 12, and the fitting parameters (i.e. α, and β) are

given in Table 4.

381

4 MODELLING STRESS-STRAIN BEHAVIORS

The strain stabilization and hardening behavior of specimens under high confining pressures

(i.e. $\sigma_c = 50, 100, 200, 300\text{kPa}$) can be described by the Duncan-Chang model (i.e. Eq. (4))

and shown in Figure 8.

$$q = \frac{\varepsilon_1}{a + b\varepsilon_1} \tag{4}$$

where a and b are model parameters. According to Gutierrez et al. (2008), Moniz (2009), and

Ladd et al. (1977), $1/a$ is the slope of the initial curve and equals the undrained elastic

modulus, E_u. $1/b$ is the ultimate deviator stress and indicates the undrained shear strength, q_u.

Fitting parameters and R^2 are summarised in Table 5.

17

391

Extending the concepts of the Duncan-Chang model, an empirical model Eq. (5) was

proposed to describe the strain-softening behavior of specimens subjected to different FT

cycles which are observed from CU and UC tests.

$$q = \frac{\varepsilon_1}{a+b\varepsilon_1} \lambda \left[\ln \left[2.718 + (10^{10\varepsilon_1} / \kappa)^{-n} \right] \right]^m \qquad (5)$$

where λ, κ, n, m, are model parameters. λ is related to the ratio of residual strength to peak

strength, κ, n, and m are the model parameters related to the axial strain at peak deviator

stress, the slope of descending portion of the stress-strain curves, and the axial strain at

residual deviator stress.

The fitting curves are shown in Figures 6 and 8 and fitting parameters are summarised in

Table 6 highlight good agreements between the measurements and the predictions. The

residual axial strain and corresponding residual deviator stress and the subsequent horizontal

section of stress-strain curves were well described.

5 CONCLUSIONS

In this paper, the influence of multiple FT cycles on the microstructure and mechanical

behaviors (including volumetric behavior, stress-strain behavior, shear strength parameters,

and elastic modulus during consolidated undrained shearing and shear strength and

unloading-reloading modulus during unconfined shearing) of an expansive soil was

investigated from experimental studies. The following observations and conclusions were

derived.

(i)   The compaction-induced macro-structures are altered in the range of 5 to 250 microns

due to the influence of FT cycles. Besides, FT cycles introduce cracks into the soil

structure. It is important to note that FT cycles have a minor influence on the

416   micropores with diameters less than 5 microns. The experimental results suggest that

417   soil swelled during the FT cycles. The volumetric behaviors become elastic after

418   approximately 4 cycles during FT treatments.

419   (ii)   The q_u, $E_{1\%}$, and $S_{u1\%}$ obtained from unconfined compression tests decrease

420   significantly with increasing N_{FT}, especially during the initial two FT cycles, and reach

421   equilibrium after approximately 4 to 6 FT cycles. The values of q_u, $E_{1\%}$, and $S_{u1\%}$ for

422   saturated specimens are much smaller than the ones of unsaturated soil specimens for

423   the same N_{FT}.

424   (iii)   The q_u, E_u, c, and ϕ obtained from consolidated undrained triaxial tests reduce due to

425   the influence of FT cycles; however, these are notably constant after 6 FT cycles.

426

427   A simple empirical model is developed to describe the strain-softening behavior of

428   stress-strain curves obtained from CU and UC shearing under low stress levels of specimens

429   undergoing 0, 1, 4, 10 FT cycles. The performance of this model is verified by the test results.

430   The model presented in this paper could be a useful tool in the numerical analysis of the

431   strain-softening behaviors that can be derived from the stress-strain curves.
