Abstract

Aiming to enhance therapeutic efficiency of lutein, lutein loaded chitosan-sodium alginate (CS-SA) based nanocarrier composite (LNCs) were prepared and evaluated for lutein bioavailability and pharmacokinetics in diabetic rats in comparison to micellar lutein (control). Further, cytotoxicity, cellular uptake and protective activity against H₂O₂ induced oxidative stress in ARPE-19 cells were studied. Results revealed that LNCs displayed maximal lutein AUC in plasma, liver and eye respectively in normal (3.1, 2.7 and 5.2 folds) and diabetic (7.3, 3.4 and 2.8 folds) rats. Lutein from LNCs exhibited a higher half-life time, mean residence time and slow clearance from the plasma, indicating prolonged circulation compared to control. In ARPE-19 cells, pre-treatment with LNCs (10 µM) have significantly attenuated H₂O₂ induced cell death, intracellular ROS and mitochondrial membrane potential compared to control. In conclusion, LNCs improve the lutein bioavailability in conditions like diabetes, diabetic retinopathy and cataract to curtail oxidative stress in retinal cells.

Introduction

Lutein (β,ϵ -carotene-3,3'-diol; C₄₀H₅₆O₂), referred as macular pigment, supports visual functions owing to its antioxidant, anti-inflammatory and anti-angiogenic properties. Lutein plays a vital role in ameliorating age-related macular degeneration, cataract (ocular complications) and diabetes mediated retinopathy due to radical scavenging property (Bernstein et al., 2016; Hemalatha, Naveen, & Baskaran, 2019; Sharavana & Baskaran, 2017). Henceforth, lutein has gained prominence in food and pharma application in treating eye-related complications (J. Chang et al., 2018; Rafi, Kanakasabai, Gokarn, Krueger, & Bright, 2015; Wu et al., 2015). Unfortunately, human cannot synthesize lutein *de novo* and hence has to be acquired through dietary sources or supplements. Moreover, lutein being mostly matrixed with food factors impedes bioavailability (Lienau et al., 2003). Therefore, to meet the daily requirement of lutein, the Joint FAO/WHO Expert Committee on Food Additives (Joint, Additives, & Organization, 2005) revised the recommendation of daily lutein intake from 2-6 mg/Kg body weight to 6-12 mg/kg body weight. Though, it has been reported that the effective dose of lutein essential to prevent ocular complications is much higher than the value recommended by JECFA (Frede et al., 2014). Consequently, various commercial lutein formulations have emerged in the market to tackle its food security. Besides, studies have shown that lutein bioavailability is poor owing to its hydrophobic nature, lower aqueous solubility, stability, sensitive to light, heat and oxygen tension because of unsaturated bonds (Boon, McClements, Weiss, & Decker, 2010; Kotake-Nara & Nagao, 2011). These constraints limit lutein application in the food and pharma industries. Since the level of daily dietary intake of lutein falls short to achieve benefits, approaches to upsurge lutein bioavailability and distribution to target tissues could yield higher health benefits.

To achieve an efficient lutein bioavailability, target delivery and efficacy to fight against macular degeneration, cataract and retinopathy require newer strategies. Many techniques have been emerged to enhance the stability, solubility and bioavailability of lutein. Among several techniques, nanotechnology is currently used effectively in food, cosmetic and pharmaceutical applications with newer biodegradable polymeric carriers along with suitable lipids to enhance pharmacokinetics and biological activity of lipophilic molecule lutein (Kumari, Yadav, & Yadav, 2010; Ranganathan, Hindupur, & Vallikannan, 2016). Previously, we have reported that low molecular weight chitosan and PLGA (Poly Lactic-co- Glycolic Acid) nanocarriers system enhanced lutein and fucoxanthin bioavailability in mice (Arunkumar, Prashanth, & Baskaran, 2013; Ranganathan et al., 2016; Ravi & Baskaran, 2015). We have also reported characteristic features and the safety of chitosan-alginate-oleic acid-based nanocarrier system (Toragall, Jayapala, & Vallikannan, 2020).

Previously, we have reported an inclusion of oleic acid (OL) in micelles and nano preparation improved intestinal absorption of β -carotene, lutein and fucoxanthin and their levels in plasma and tissue including retina (Mamatha & Baskaran, 2011; Ranganathan et al., 2016; Sugawara et al., 2001). Polymer and lipid-based carriers are two major bioactives and drug delivery systems that are widely used across the food and pharma industries (Ravi & Baskaran, 2015; Vishwanathan, Wilson, & Nicolosi, 2009). These delivery systems have their own leads and drawbacks. Hence, in the present study, we have designed a lutein loaded nanocarrier system (LNCs) using natural polymers chitosan (CS) and sodium alginate (SA) to protect lutein from the acidic pH of the stomach and intestine. OL was added to the LNCs to provide a lipid core and to enhance the lutein solubility and bioavailability. The

prepared LNCs are expected to display superior encapsulation efficiency, stability, solubility, bioavailability, bioefficacy and sustained systemic circulation of lutein.

Based on the available literature and our previous findings, we have hypothesized that LNCs designed in the present study would enhance the intestinal absorption, pharmacokinetics and bioavailability of lutein. The objective of the study was to (1) examine the effect of LNCs on lutein bioavailability (plasma and retina response) and pharmacokinetics in control and diabetic rats and (2) to find out protective effect against H₂O₂ induced oxidative stress in ARPE-19 cells compared to physiologically relevant vehicle (lutein mixed micelles).

Materials And Methods

Materials

Standard lutein (96%), chitosan and oleic acid were purchased from Himedia (Mumbai, India), sodium alginate was obtained from Sigma Aldrich (Bangalore, India). Low-density lipoproteins (LDL) and high-density lipoproteins (HDL) were purchased from Agape Diagnostics (Ernakulam, India). HPLC and analytical grade solvents methanol, acetonitrile, dichloromethane, acetone, sodium sulfate, potassium hydroxide, ammonium acetate, and other chemicals were purchased from Sisco Research Laboratory (Mumbai, India).

Structural characteristics of polymers chitosan (CS) and sodium alginate (SA)

Characteristics of CS (degree of deacetylation $\geq 75\%$ and viscosity 348 cP) was measured at 1% CS (*w/v*) in the water at 25 °C, 100 rpm and 34.8% torque using the spindle number 3, Brookfield viscometer, RV DV-II+Pro, USA and the intrinsic viscosity $[\eta]$ was calculated as per [Chattopadhyay & Inamdar \(2010\)](#). Based on intrinsic viscosity, average molecular weight ($M_w \approx 213$ kDa, 1% *w/v* solution) of chitosan was calculated using the Mark-Houwink equation $[\eta] = K M^\alpha$, where, $K = 3.5 \times 10^{-4}$ and $\alpha = 0.76$ (1% *w/v*, in 0.5% acetic acid solution ([Kumar & KV, 2019](#))).

Characteristics of SA (viscosity 175 cP) was measured at 1% SA (*w/v*) in the water at 25 °C, 100 rpm and 17.5% torque using the spindle number 1 (Brookfield viscometer, RV DV-II+Pro, USA), FTIR spectroscopy (Bruker, Tensor II, Germany) was used quantify the mannuronate/gulonate (M/G) ratio (1.84) of SA ([Chandia, Matsuhira, & Vásquez, 2001](#); [Dodero, Vicini, Alloisio, & Castellano, 2019](#); [Filippov & Kohn, 1974](#)) in particular, correlating absorption band at 808 cm^{-1} assigned to M units and 787 cm^{-1} to G units. The interaction of chitosan-sodium alginate polymer composite is given in Figure 1.

Purification of lutein

Lutein was extracted and purified from fresh marigold (*Tagetes erecta*) flower petals with ice-cold acetone containing 0.1% butyl hydroxyl toluene for experimental use. In brief, the acetone extract was filtered over anhydrous sodium sulfate to remove moisture and saponified with 30% methanolic potassium hydroxide in the dark for 3 h at room temperature (27 ± 2 °C) and phase separated with distilled water. The carotenoids rich hexane phase was collected, pooled, concentrated, and loaded onto an activated silica column (60•120 mesh). A mixture of dichloromethane: methanol (1:1, *v/v*) was used to elute lutein and its purity was confirmed by high-performance liquid chromatography (HPLC) and liquid chromatography- mass spectrometry (LC-MS) ([Lakshminarayana, Raju, Prakash, & Baskaran, 2009](#); [Toragall, Jayapala, & Vallikannan, 2020](#)).

Preparation of nanocarrier system by ionic gelation method

The lutein loaded nanocarrier (LNCs) system was prepared by the ionotropic gelation method ([Farshid & Lakshmi, 2017](#)) with modification ([Toragall, Jayapala, & Vallikannan, 2020](#)). In brief, chitosan (1 mg/mL) was dissolved in 0.1% acetic acid solution. Purified lutein was mixed with oleic acid at 1:2 ratio with 0.1% tween 80 and added to the chitosan solution in a dropwise manner under continuous stirring at 800 rpm using a magnetic stirrer (REMI CM-101 plus, India) for 30 min. Sodium alginate solution (0.5 mg/mL) was added to the mixture and stirred for 30 min and the mixture was sonicated for 15 min (probe sonicator, PCI, Mumbai,

India) at 50 Hz on the ice followed by high-speed homogenization (ULTRA- TURRAX-T25, IKA, USA) at 15000 rpm for 10 min that resulted in LNCs.

Particle size and zeta potential of LNCs

Dynamic light scattering (DLS) was used to determine the hydrodynamic size of LNCs. The LNCs was diluted (10 fold) with triple distilled water to avoid the multiple scattering phenomena results from the concentrated sample and subjected to analysis. The particle size, zeta potential and polydispersity index (PDI) of LNCs were examined by zetasizer (Nano-ZS 90, Malvern Instruments Ltd, Worcestershire, UK). Measurements were made in triplicates at 90° scattering angle at a temperature of 25°C.

Shape and morphology of LNCs

The surface and surface morphology of LNCs were analyzed by scanning electron microscopy (SEM) (ZEISS EVO, Thornwood, USA) operated at a voltage of 5-15kV. In brief, a drop (2-5 µL) of nanosuspension or a small quantity of spray-dried powder (0.1-0.2 mg) was mounted on a circular metal SEM stub with a double-sided sticky tape, air-dried at room temperature. Air-dried samples were sputter coated with gold and allowed to dry at room temperature and observed under SEM in secondary electron imaging mode (Sadiq et al., 2016). The shape and size of LNCs were confirmed by transmission electron microscopy (TEM) examination (Titan Themis 300kV from FEI, Thermo Scientific™. Waltham, Massachusetts, USA). In brief, an aqueous nanosuspension sample of LNCs was deposited upon a carbon-coated copper grid and air-dried for 1 min. Then, the sample was instantly stained with 2% phosphotungstic acid, randomly scanned and photomicrographs were taken at different magnification.

Lutein encapsulation efficiency

The encapsulation efficiency (EE) of lutein was determined by centrifuging nanosuspension (1mL) at 14000 rpm for 20 min at 4 °C (Eppendorf, 5810R, Germany). The concentration of unencapsulated lutein was extracted and measured by using HPLC in comparison with standard lutein (Lakshminarayana, Raju, Krishnakantha, & Baskaran, 2006). EE was calculated as per the formula given below:

$$\text{Lutein EE (\%)} = \frac{\text{IL} - \text{LS}}{\text{IL}} * 100$$

where, IL is initial lutein concentration, LS is lutein concentration in the supernatant.

Lutein- mixed micelles preparation

Mixed micelles were prepared as per (Lakshminarayana et al., 2006). In brief, monooleoyl glycerol (2.5 mM), oleic acid (7.5 mM), sodium taurocholate (12 mM) and lutein (600 µM) were dissolved in methanol separately and mixed to reach the final concentration. The solvent was evaporated using nitrogen gas, and the mixture was resuspended in phosphate buffer saline (pH 7.4) with sonication (PCI, Mumbai, India) for 30 min to obtain mixed micelles. Lutein concentration in the mixed micelles and LNCs was confirmed by HPLC before using for cell culture and animal studies.

Pharmacokinetic study

Animals

The animal experiment was carried out after due clearance from the CFTRI animal ethics committee (FT/AHF/AI/129/2019). Pharmacokinetic studies were carried out on healthy male Wistar rats (age, 6-8 weeks), weighing 150 ± 10 g, which were housed individually in polypropylene cages. Animals were maintained in an environmentally controlled atmospheric condition at 28 ± 2 °C with 12 h light: dark cycle and given free access to feed (Champaka feeds and foods, Bengaluru, India) and water at CFTRI animals house facility.

Diabetes induction

For diabetes induction, a single dose of STZ (38 mg/kg body weight) was injected intraperitoneal to the overnight fasted (n = 20) rats. Rats were given free access to feed and water. Prior to STZ injection, rats were acclimatised for 1 week and fasting blood glucose was examined (Sharavana & Baskaran, 2017). Rats with > 200 mg/dL blood glucose concentration were considered as diabetic rats (Sharavana & Baskaran, 2017).

Dosing

Micellar (control) and LNCs lutein concentration was determined as per (Toragall, Jayapala, & Vallikannan, 2020). In brief, 1 mL of LNCs or mixed micelles was extracted for lutein and confirmed the purity by HPLC prior to intubation to animals. Lutein concentration in LNCs was determined based on the encapsulation efficiency. Rats were gavaged (0.2 mL) lutein (600 µM) either in mixed micelles or LNCs.

Bioavailability of lutein from LNCs

Rat (n = 40) were divided into two groups as control (n = 20) and diabetic (n = 20) and were fasted overnight with free access to water. Rats in each group was divided into 2 sub-groups (n = 10/group) and gavaged 600 µM lutein (0.5 mL) either mixed micelles (control) or LNCs. Blood (200 µL) was collected at different time points (2, 4, 8, 12 and 16h) of post-dose through the retro-orbital route from three animals into 1.5 mL eppendorf tube coated with heparin (Table 1). Plasma was collected by centrifugation (Eppendorf, 5810R, Germany) at 2900 rpm at 4°C for 10 min and organs were harvested, snap-frozen and stored at -80 °C until analysis.

Table 1. Experimental design adopted for the pharmacokinetic study

Groups	Sub-groups	No. animals	Lutein dose	Blood collection intervals (h)
Control	Mixed micelles	10	600 µM	0, 2, 4, 8, 12, 16
	LNCs	10		
Diabetic	Mixed micelles	10		
	LNCs	10		

Cell culture, maintenance and cell viability assay

Human retinal pigment epithelial (ARPE-19) cell line was procured from the American Type Culture Collection (ATCC® CRL-2302™) (Manassas, Virginia, USA) and was maintained in Dulbecco's Modified Eagle Medium: Nutrient Mixture F-12 (DMEM/F12) with 10% heat-inactivated FBS, penicillin (100 U/mL) and streptomycin (100 µg/mL). Cells were maintained at 37 °C in a humidified atmosphere with 5% CO₂. The percent viability was measured by MTT assay (3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide). Briefly, cells were seeded into 96 well plates at 2 × 10⁴ cells per well and were treated with either micellar lutein or lutein (0, 1, 5, 10, 15, 15, 20 and 50 µM) loaded NCs for 24 h. Control cells received fresh medium and vehicle control received LNCs without lutein were compared with LNCs treatment groups. Each well was then added with 10 µL MTT and incubated for 3 h at 37°C, media was removed, and DMSO (150 µL) was added to solubilize the MTT formazan and read at 520 nm using a multimode microplate reader (Infinite-M200 PRO, Tecan, Switzerland).

Cellular lutein uptake

To examine the cellular lutein uptake, ARPE-19 cells (3 X 10⁶ cells/mL) in 60 mm² cell culture dishes were treated with either micellar lutein or LNCs for different time interval (0, 3, 6, 12, 18, 24 h) in normal condition (without any stress) and under H₂O₂ (150 µM for 2h) induced oxidative stress condition as evidenced in diabetes in cells and processed for lutein extraction and analysed by HPLC (Lakshminarayana et al., 2009; Toragall, Jayapala, & Vallikannan, 2020).

Measurement of intracellular ROS

Oxidative stress, result of undue generation of ROS and the subdual of ROS by antioxidant defense system, is associated with the development of retinopathy in diabetes. Hence, intracellular ROS level in the H₂O₂ treated cells exposed to either micellar lutein or LNCs was quantified using the rate of conversion of DCFH-DA to fluorescent DCF (Driver, Kodavanti, & Mundy, 2000). In brief, after the treatment, cells were washed twice with 1X PBS, incubated with 10 µM of DCFH-DA for 30 min at 37 °C in dark, washed three times with 1X PBS, re-suspended and PBS (0.5 mL) was added to each well and images were acquired using the inverted fluorescent microscope (Model 1X73, Olympus Corp., Japan). The intensity of fluorescence was analysed by Image J software. The data were expressed in percentage fluorescence relative to the control cells.

Mitochondrial Membrane Potential Assay (DYm)

In disease/disorder, mitochondrial damage in retinal pigment epithelium is initiate for the degeneration of RPE. To test this, mitochondrial membrane potential of RPE cells treated with LNCs or mixed micelles was measured by JC-1 (5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolylcarbocyanine iodide, cationic dye (Sakamuru, Attene-Ramos, & Xia, 2016). In brief, ARPE-19 cells at 2x10⁶ cells/mL in 60-mm² plates were grown up to 80% confluency and treated with either micellar lutein or LNCs (10 µM) along with polymer control. After 24 h, cells were treated with H₂O₂ (150 µM) for 2 h and cells were harvested, washed, and stained with 10 mM JC-1 at 37°C for 15 min in the dark. At a relatively high

DYm, JC-1 dye showed clump and yielded red fluorescence, whereas at a low DYm, JC-1 confined in the cytoplasm in green fluorescence. Signals were quantified by measuring red fluorescence (excitation 560 nm, emission 595 nm) and green fluorescence (excitation 485 nm, emission 535 nm) using an Infinite M200 PRO Multimode Microplate reader. Mitochondrial membrane potential (DYm) was calculated as the ratio of JC-1 red/green fluorescence intensity and values were normalised to control group. The fluorescent signal in the cells was also observed and recorded with an inverted fluorescent microscope (Model 1X73, Olympus Corp., Japan). The fluorescent signal in the ARPE-19 cells was also observed and recorded with a fluorescent microscope.

Quantitation of lutein from plasma/RPE cells

Lutein was extracted from plasma or ARPE-19 cells as per Laxshminarayana et al. (Lakshminarayana et al., 2006; Toragall, Jayapala, Muthukumar, & Baskaran, 2020). In brief, to the plasma (0.1 mL), or cells (1 mL homogenate) DCM:MeOH (3 mL, 2:1, v/v) with 2 mM tocopherol and hexane (1.5 mL) was added, the mixture was vortexed and centrifuged at 3000 rpm at 4 °C for 6 min. Lutein released in the upper phase was collected and repeated extraction for 3 times. Extracts were pooled, evaporated to dryness using the nitrogen gas and dissolved in reconstituted 50 µL mobile phase (ACN:DCM:MeOH, 60:20:20 v/v/v) containing 0.1% ammonium acetate. HPLC (LC-10A vp; Shimadzu, Kyoto, Japan), equipped with photodiode array detector (SPD-M20A), separated on Phenomenex RP-18 (ODS) column (250 mm x 4.6 m; 5 µm) isocratically (1 mL/min flow rate) eluted with the mobile phase and detected at 450 nm (Shimadzu Class-VP version 6.14 SP1 software) and further, confirmed by LC-MS analysis (Lakshminarayana et al., 2009; Toragall, Jayapala, & Vallikannan, 2020).

Statistical analysis

The data are represented as ± SD (n=3). Significance between groups interpreted by one way ANOVA with Post Tukeys test with p≤0.05 is considered as significantly different using graph pad Prism (v. 5.0). The absorption kinetics was calculated with non-compartmental analysis online software of Pharma Consulting Company, PKMP software (v. 1.03.017) and AUC with trapezoid rule with linear interpolation.

Results And Discussion

Purity of lutein

The lutein extracted from marigold flower petals found to be ≥ 96% pure, confirmed by HPLC and HRMS (Supplementary Fig. 1). The purified lutein was used for the preparation of lutein mixed micelles and LNCs.

Particle size, zeta potential and PDI measurement

The DLS characterized LNCs found to have a mean particle size of 98 ± 5 nm and polydispersity index of 0.27 ± 0.01 (Fig. 2A & 1F), which is comparatively lesser than earlier report (Ranganathan et al., 2019). Ranganathan et al. (2019) have reported lutein nanocarrier with synthetic polymer PLGA (+PL-phospholipid) with a larger particle size of 140 ± 6 nm. Another interesting study by H. Feng et al. (2017) reported that lutein loaded emulsions prepared using corn fiber gums also showed larger particle size 160-200 nm with lower -5.86 to -10.6 mV zeta potential. Similarly, Ma, Yuan, Yang, Wang, and Lv (2020) reported that lutein encapsulated zein/tea saponin composite nanoparticles displayed the larger particle size 117.9-231.1 nm. Also, Jiao et al. (2018) reported that lutein encapsulated zein-derived peptides as nanocarriers showed more massive particle (297.7 - 400 nm) than the present findings with natural polymers (CS and SA). Further, the smaller size of LNCs established in the current study may be due to the ionic gelation method adopted for the preparation (Fig.1).

Smaller particle size and surface charge govern the stability, pharmacokinetics and bio- distribution of lutein in the body. Though the ocular barrier controls the exchange of hydrophobic molecules between the blood and ocular tissues, the size of chitosan-based NCs being less than 100 nm, found to have higher ocular biodistribution without disturbing the integrity of the epithelial cells (Mohammed, Syeda, Wasan, & Wasan, 2017). In addition, since the size of the LNCs was 98 nm, it was found to easily cross the physiological (intestinal barrier and blood-retinal barrier) barriers. This could be due to the higher interfacial area of smaller particle size of LNCs, which led to maximum absorption of lutein with slow and controlled release compared to bulk materials and mixed micelles (Niamprem, Rujivipat, & Tiyaboonchai, 2014; Ranganathan et al., 2019). This could be the possible reason for the higher plasma and RPE levels of lutein from LNCs than the micellar lutein.

Zeta potential of nanoparticle represents the surface charge (Ridolfo, Williams, & van Hest, 2020). Higher the zeta potential (positive or negative) specifies more excellent stability of nanoparticles in the suspension with lower aggregation due to strong repellent forces existent on the surface (Vonarbourg et al., 2009). Tween 80 added in the LNCs preparation has also spiked up the steric stability (Wissing, Kayser, & Müller, 2004). The zeta potential of LNCs was 38 ± 4 mV, signifying the higher stability and homogeneity of LNCs in aqueous solution. Positively charged LNCs have the advantages in targeted drug delivery due to the negatively charged electrostatic properties of the cell surface (Chen et al., 2016; Du et al., 2018). Since the glycoproteins of the intestinal mucosa are negatively charged and the designed LNCs are positively charged, mucoadhesion of LNCs can be obtained, thus facilitating the permeation of LNCs through the intestinal barrier. Similarly, LNCs can be crossed over the retinal barrier (Honary & Zahir, 2013). This could be the reason for higher levels of lutein in the plasma and RPE-19 cells indicating higher bioavailability and cellular uptake of lutein from LNCs than from mixed micelles.

Scanning electron microscopy and Transmission electron microscopy of LNCs

The surface morphology of nanoparticles plays a crucial role in drug delivery/release (Mukerjee & Vishwanatha, 2009). SEM micrographs of LNCs showed a discrete distribution of cluster free particles with divergent spherical shape (Fig. 2D & 2E). LNCs are smooth surface with less than 100 nm size (Fig. 2F) as compared to PLGA (+PL) nanoparticle that are clustered in nature with spherical in shape and 200 nm size (Ranganathan et al., 2019). The size and surface morphology were further confirmed by TEM (Fig. 2B & 2C). Therefore, smooth morphology and smaller particle size may be the reason for higher plasma and cellular levels of lutein from LNCs compared to mixed micelles (Fig. 3). However, the average particle size perceived by TEM was significantly smaller than that of DLS detection, which was due to mainly the hydration status or hydrodynamic size. At the same time, the TEM samples were dried before the examination. Acevedo Fani et al. (2017) also found that droplet sizes examined under TEM were in good agreement with those obtained by DLS. Besides, TEM reflected the local particle size of the LNCs. In contrast, DLS reflected the average particle size of LNCs, but the particle size distribution of DLS (Fig. 2E) has very good agreement with TEM results.

Pharmacokinetic/bioavailability of lutein from LNCs in rats

The postprandial plasma, liver and eye lutein responses after a single dose (600 μ M) of micellar lutein (control) and LNCs in normal rats are shown in Fig. 3A, 3B and 3C. Detectable level of lutein in the plasma was at 2 h of post-oral administration of micellar lutein. The time for absorption maxima (T_{max}) was at 4 h with area under curve (AUC) value of 1995.1 ± 39 ng /mL/16 h and concentration maxima (C_{max}) of 67.66 ± 6.8 ng/mL at T_{max} (Table 2). Despite the same T_{max} (4 h), the C_{max} (182.85 ± 16.5 ng/mL) and AUC (1158.5 ± 43 ng /mL/16 h) of lutein from LNCs found to be higher by 2.7 and 3.10 folds ($P \leq 0.05$)

compared to control. Results show a detectable level of circulating lutein in the LNCs fed group even after 16 h displaying a slow and controlled release property of polymer (CS-SA) with oleic acid nanocomplex which is an important characteristics of nanocarriers (Mukerjee & Vishwanatha, 2009). In addition, a greater (half lifetime) $T_{1/2}$ (3.62 ± 0.2 h), mean residence time (MRT) (17.64 ± 2.0 h) and slower clearance (Cl) (0.0054 ± 0.001 ng/(ng/mL)/h) from the plasma were evident in the LNCs group indicating a prolonged circulation of lutein rather than rapid clearance (Li & Huang, 2008). These results further add to the slow and sustainable release of lutein from LNCs compared to the mixed micelles. Seto, Ueno, Suzuki, Sato, and Onoue (2019) reported that a relatively high dose of lutein nanocrystal (230 nm) formulation (300 mg/kg) was orally administered to the healthy rats showed poor absorption of lutein was observed based on the pharmacokinetic profiles (C_{max} 11.3 ± 2.2 ng/mL and AUC 146 ± 24 ng/mL) and decreased accumulation of lutein in the retinal tissue (11.5 ng/g). In contrast, the present study results revealed the higher LNCs lutein pharmacokinetic profile (C_{max} 182.85 ± 16.5 ng/mL and AUC 1158.5 ± 43 ng /mL) and greater tissue accumulation of lutein in the retinal tissue (39.84 ± 6.4 ng/mL) might be due to the smaller particle size (98 nm; Fig. 2) and higher aqueous solubility of prepared LNCs. Moreover, the inadequate dissolution behavior of crystalline lutein may be one of the causes of the poor oral absorption of lutein. Regarding oral absorption mechanisms of administered lutein, enhancement in the lymphatic transport of lutein had been observed after oral administration of solid dispersion and self-micro emulsifying system (Sato et al., 2018). In this context, the part of orally administered LNCs might have been transferred into the lymph stream from the small intestine and lymphatic transport may contribute to a gradual increase in the plasma lutein concentration after oral administration of LNCs. Further, Zhao et al. (2018) have reported that lutein-cyclodextrin multiple-component delivery system orally gavaged to healthy rats at the higher dose of 3 mg lutein (about 10 mg/kg) displayed the C_{max} of 135.8 ± 49.7 ng/mL and AUC 633.0 ± 209.7 ng.h/mL at T_{max} of 2h. In contrast, LNCs prepared in the present study showed higher C_{max} (182.85 ± 16.5 ng/mL) and AUC (1158.5 ± 43 ng /mL/16 h) even at a lower oral dose (600 μ M) despite of the different T_{max} (4h), which may be attributed to a slow and controlled release of lutein from CA-SA nanocomposite.

The C_{max} and AUC values of lutein in the liver of LNCs group displayed higher (2.5 and 2.7 fold) compared to control ($P \leq 0.05$) despite the identical T_{max} (8 h). Similarly, higher C_{max} and AUC values of lutein were obvious in the eyes (3.3 and 5.2 fold) of LNCs group compared to control (Table 2). Results establish that the lutein bioavailability (plasma response) and distribution to the target organs (eye and liver) from LNCs were higher, may be due to the hydrophobic lutein and polymers. D. Liu, Mori, and Huang (1992) have studied the biodistribution of the radioisotope-labelled liposomes with 30-400 nm size in a mice model upon intravenous injection. They have found that the nanoparticles with a mean diameter of 100 nm revealed prolonged blood circulation and higher liver uptake. The present study also shows higher levels of lutein from LNCs in circulation and liver that could be due to the smaller size of LNCs (Fig. 2D). After oral administration of LNCs, it was found that lutein distributed and accumulated mostly in the liver, followed by the eye (Fig. 3 B & 3C). This tendency is almost consistent with previous reports (Sato et al., 2011; Yonekura, Kobayashi, Terasaki, & Nagao, 2010). Also, an interesting study by D. Chang et al. (2018) reported that the nanocrystal formulation of lutein (10 mg/kg BW) administered orally to rats showed a higher C_{max} (455.85 ± 59.76 ng/mL) at T_{max} of 3h. In comparison, the present study results showed lower C_{max} (182.85 ± 16.5 ng/mL). The possible reason for higher C_{max} could be due to the higher oral dose of lutein nanocrystal (10 mg/kg BW) administered in the above mentioned study. Moreover, a lower dose (600 μ M or 0.5 mg/kg BW) of LNCs administered in the present study displayed a relatively higher C_{max} compared to the study as mentioned earlier (D. Chang et al., 2018). Further, the lipid composition of any preparation plays a vital role in the carotenoid bioavailability. Use of oleic acid in the LNCs found to help in better intestinal uptake of lutein (Lakshminarayana et al., 2006). The higher intestinal absorption of lutein from LNCs with oleic acid after a week human trial showed ~ 1.3 -fold higher bioavailability compared to lutein delivered in pills (Vishwanathan et al., 2009). Shanmugam et al. (2011) have reported higher bioavailability of lutein (4-11 fold) from oleic acid microemulsion in rats. These findings demonstrate that the inclusion of oleic acid in LNCs supports higher lutein bioavailability.

In order to find out the pharmacokinetics of lutein from LNCs in the diabetic model compared to the control model, the groups were intubated a single dose (600 μ M) of micellar lutein (control) or LNCs and the results of postprandial plasma, liver and eye lutein responses are shown in Fig. 3D, 3E and 3F. No difference was found in the pattern of pharmacokinetics (absorption and tissue distribution) of lutein from micelles and LNCs fed to diabetic rats. However, lower lutein concentration was found in the diabetic rats compared to normal healthy rats. The C_{max} (67.66 ± 6.8 ng/mL) and AUC (373.4 ± 26 ng/mL/16h) of lutein from the LNCs group were found to be significantly higher (C_{max} , 182.85 ± 16.5 ng/mL; AUC, 1158.5 ± 43 ng/mL/16h) by 2.7 and 7.3 folds than the micellar group (Table 3). Nevertheless, the T_{max} (4 h) is similar in both groups. Interestingly, plasma lutein was higher

even after 16 h in the diabetic rats fed on LNCs signifying a steady-state release (Fig. 2F) suggesting controlled lutein release from nanocomplex (Mukerjee & Vishwanatha, 2009). Alike, higher T_{1/2} (6.60 ± 0.8 h), MRT (8.0 ± 1 h) and lower Cl (0.088 ± 0.01 ng/(ng/mL)/h) of LNCs indicate sustained circulation of lutein in diabetic condition, may be to protect the cells from oxidative stress caused by diabetes (Li & Huang, 2008). Results further suggest that owing to sustained benefits, LNCs prepared in this study could be considered for delivery of lutein to manage diabetic mediated complications like cataract and retinopathy (Padmanabha & Vallikannan, 2018). As in the case of plasma lutein, the liver C_{max} and AUC of lutein from LNCs have shown significantly higher by 2.6 and 3.4 folds compared to the micellar group (Table 3, Fig. 2E). Similarly, despite the same T_{max} (12 h), lutein level in the eyes of LNCs group was higher by 4.04 and 2.80 folds (C_{max}, 28.89 ± 2.9 ng/g; AUC, 1588 ± 43.1 ng/g/16h) compared to the control group.

Macular pigment density is well correlated with dietary intakes and plasma concentrations of lutein (Hammond Jr et al., 1996; T Landrum et al., 1997). LNCs constructed could be a prospective therapeutic tool for the treatment of ocular complications owing to higher lutein bioavailability and radical scavenging property. Wang et al. (2007) have described that 52% of lutein was transported to the retina by HDL and 22% by LDL from dietary lutein and zeaxanthin in AMD patients. Connor, Duell, Kean, and Wang (2007) have also reported similar findings that HDL-deficient WHAM Chicks having a mutant ABCA1 transporter, HDL plays a prime role in the transport of lutein to the retina. However, in the STZ induced diabetic rats, lower levels (22%) of HDL (Fig. 4A) and higher (15%) levels LDL (Fig. 4B) compared to normal healthy rats were observed. However, on treatment with LNCs, the HDL level was reverted to the normal levels. This could be the possible reason for the higher retinal level (eye C_{max}- 28.89 ± 2.9 ng/mL and AUC - 1588 ± 43.1 ng/g/16h, Table 3) of lutein from LNCs.

An oral administration of micellar lutein and LNCs to rats peaked maximum in the plasma at 4 h, as reported earlier by Lakshminarayana et al. (2006) and Ranganathan et al. (2019). Further, the tissue biodistribution of lutein from mixed micelles and LNCs found in this study is also in line with other pharmacokinetic studies (Kamil et al., 2016; Ranganathan et al., 2019; Sato et al., 2011). They have reported an accumulation of lutein in the liver and eyes of rats fed lutein-PLGA-NCs orally or intravenously. Overall, the pharmacokinetic pattern of absorption and tissue distribution of lutein from mixed micelles and LNCs in the diabetic rats were almost similar to normal healthy rats. Arunkumar et al. (2013) have reported that an acute dose (200 µM) of lutein loaded chitosan nanocapsules to mice displayed 2 fold higher lutein bioavailability (plasma, liver and eye levels) compared to micellar lutein. Results of the current study suggest that LNCs support the intestinal uptake and tissue (plasma, liver, and eye) distribution of lutein from LNCs. The bioavailability of lutein from LNCs found in the current study is significantly higher in plasma (3000 folds), liver (855 folds) and eye (739 folds) than PLGA-NCs reported by Ranganathan et al. (2019) which may be due to smaller particle size (98 nm), coating polymers (natural CS-SA) and the lipid core (oleic acid) (Lakshminarayana et al., 2006; Li & Huang, 2008). Based on the results, we propose that LNCs could be adopted to deliver lutein to target tissue like retina.

Table 2 Pharmacokinetic parameter of plasma, liver and eye responses of micellar lutein and lutein from LNCs after the single oral dose to normal healthy rats.

Parameters	Plasma		Liver		Eye

ARPE-19 cell viability

Potential cytotoxicity of LNCs to human retinal pigmental epithelial cells (ARPE-19) was examined by MTT assay. Figure 5A demonstrates that LNCs (0-50 μM of lutein) did not affect the viability of ARPE-19 cells compared to control cells. Therefore, 10 μM concentration of LNCs (1/5th) was used for the treatment in further experiments.

Protective effects of LNCs against H₂O₂ induced oxidative stress

Diabetes/hyperglycemia induces oxidative stress (OS) by generating pre radicals (Asmat, Abad, & Ismail, 2016). Hence, to find out the radical scavenging and cell protective property of LNCs, OS was induced by treating cells with H₂O₂. Therefore, initially, ARPE-19 cells were exposed to H₂O₂ (150 µM) for different time intervals up to 24 h and monitored the intracellular ROS level by DCF-DA dye to ascertain oxidative stress (Fig. 5B). The intracellular ROS has significantly increased from 1 h to 2 h and from 2 h afterward, no significant alteration was noticed. Hence, 2 h exposure time was considered for subsequent studies. To find out the protective effect of lutein, cells were treated with an equimolar concentration of LNCs and micellar lutein (10 µM) prior to exposure to H₂O₂ for 24 h which resulted in 50% cell death. Whereas, pre-treatment with micellar lutein and LNCs significantly attenuated H₂O₂ induced cell death by 63% and 79%, respectively (Fig. 5C). H. Liu et al. (2017) have reported that lutein at 10 µM has reversed the reduction of RPE cell viability under H₂O₂ persuaded OS conditions by 65.4 %. In the present study, LNCs displayed higher (79%) RPE-19 cell viability than micellar lutein, indicating greater cellular uptake and scavenging intracellular ROS. The higher efficacy of LNCs, the smaller particle size and slow and controlled lutein release from LNCs compared to micelles could be the reason for higher cell viability (Mukerjee & Vishwanatha, 2009; Niamprem et al., 2014).

Cellular Uptake of lutein

ARPE-19 cells were treated with LNCs or micellar lutein ((10 µM) to find out cellular Uptake of lutein. No reduction in the cell number or cell death was observed in LNCs treatment, demonstrating a safe level of NCs delivered. Cellular lutein uptake from LNCs was higher (17.6 ng/mg) compared to micelles (9.5 ng/mg) at 18 h in the H₂O₂ (150 µM for 2 h) treated cells (Fig. 6A). Over the period of 24 h treatment, in control cells (not exposed to H₂O₂), there was a non-significant decrease in the lutein uptake (6.3 and 15.6 ng/mg) from mixed micelles and LNCs. As discussed earlier in animal experiment, the higher lutein uptake from LNCs may be due to their nanosize and higher surface to volume ratio (Deming & Erdman, 1999; S.-S. Feng, 2004; Mukerjee & Vishwanatha, 2009; Niamprem et al., 2014). It is well documented that particle size plays a critical factor in cellular uptake, release kinetics and stability of active compounds (S.-S. Feng, 2004; Niamprem et al., 2014). However, cellular lutein uptake patterns from LNCs and mixed micelles are similar between H₂O₂ treated and control ARPE-19 cells. Interestingly, lutein uptake is significantly higher by 2 fold (12.1 ng/mg) from mixed micelles and 1.5 folds (21.6 ng/mg) from LNCs in H₂O₂ treated (Fig.6B) groups compared to control cells and H₂O₂ (150 µM for 2 h) treatment did not cause a reduction in the cell number (Fig. 6C). The possible reason for high cellular lutein uptake from LNCs under H₂O₂ could be due to enhanced cell permeability persuaded by the H₂O₂.

Since lutein uptake at 18 h was maximum, 18 h treatment time was considered as the working parameters for the subsequent studies.

LNCs attenuates the H₂O₂ generated oxidative stress

The imbalance between antioxidants and pro-oxidants in hyperglycemia leads to oxidative stress owing to the release of ROS beyond the limits of clearance from circulation and cells. Such a condition results in functional and morphological impairment in retinal pigment epithelium (RPE), endothelial cells, and retinal ganglion cells (He et al., 2014; Sharavana & Baskaran, 2017). We have hypothesized that the delivery of lutein as LNCs could greatly modulate the intracellular ROS than micellar lutein in ARPE-19 cells under H₂O₂ induced oxidative stress. ROS levels were measured in ARPE-19 cells upon H₂O₂ treatment and followed by treatment with either micellar lutein or LNCs (Fig. 7). Results showed 5.3 fold increase in ROS level in H₂O₂ treatment compared to control (no H₂O₂ treated) and vehicle control, indicating that vehicle has no role in ROS release. Cells pre-treated with micellar lutein or LNCs (10 µM) significantly reduced the intracellular ROS level by 2 folds suggesting that LNCs had greatly ameliorated the intracellular ROS compared to micellar lutein, might be due to higher cellular lutein uptake from LNCs. Other possible reasons for ROS lowering effect could be the slow and sustainable release of lutein from natural polymers CS and SA (S.-S. Feng, 2004; Niamprem et al., 2014). Chae, Park, and Park (2018) also reported that lutein (10 µM) treatment prior to H₂O₂ (100 µM for 2h), decreased the ROS levels (26.03%) in ARPE-19 cells. However, lutein delivered in NCs developed in the current study efficiently brought back the intracellular ROS to the normal level. We have demonstrated that LNCs suppress H₂O₂-induced oxidative stress.

LNCs attenuated the loss of mitochondrial membrane potential (DYm) induced by H₂O₂

Oxidative stress persuades detrimental alterations in mitochondria and its membrane potential (DYm) of RPE cells that can upset mitochondrial homeostasis that may be one of the central cause factors in retinal pathogenesis (Blasiak, Pawlowska, Szczepanska, & Kaarniranta, 2019). Alteration of mitochondrial membrane potential (DYm) affects its functions. To find out the role of LNCs on the up-regulation of DYm under H₂O₂ induced OS in ARPE-19 cells by examining the ratio of red/green fluorescence intensity of JC-1 staining. Exposure of ARPE-19 cells to 150 µM H₂O₂ resulted in rapid loss (49%) of DYm, as seen by an increase in the DYm fluorescence intensity (Fig. 8). Pre-treatment with micellar lutein or LNCs (10 µM) for 18 h found to attenuate DYm by 67% and 88% suggesting that LNCs render better protection and maintenance of DYm homeostasis compared to micellar lutein indicating a possible advantage of nanosize and surface charge of LNCs over the micellar lutein (S.-S. Feng, 2004; Niamprem et al., 2014).

Conclusion

LNCs developed in this study are proficient to improve the solubility and physiological stability of lutein, which could be one of the reasons for the improved intestinal uptake, plasma and tissue (retina) responses of lutein in both normal and H₂O₂ induced OS in ARPE-19 cells. However, the molecular transport mechanism of LNCs across intestinal and retinal epithelial cells needs a detailed investigation. The higher bioavailability of lutein in retinal cells and *in vitro* and rat retina *in vivo* from LNCs might be due to the nanosized (≤ 100 nm) LNCs with natural polymers CS and SA in addition to oleic acid. Higher encapsulation efficiency, stability and self-assembling property of oleic acid in LNCs have delivered greater potential towards the enhanced lutein bioavailability. Further, for the first time, to the best of our knowledge, LNCs have been prepared completely with natural polymers and examined for lutein delivery in the H₂O₂ induced OS model. However, a detailed study with hyperglycemia induced model is warranted to validate the present results. Thus, LNCs may be considered as a potential carrier system for macular carotenoid lutein to the ocular tissue to diminish OS in retinopathy, cataract and macular degeneration. Results unveil that the CS-SA-OL nanocarrier scaffold could serve as more efficient carrier than synthetic polymers or lipid alone for the delivery of lipophilic bioactive to aid AMD, cataract and diabetic retinopathy.

Figures

Figure 1

Chitosan-sodium alginate interaction scaffold

Figure 2

Particle size of LNCs measured by (A) dynamic light scattering, TEM image at (B) 100 nm and (C) 50 nm scale. (D) & (E) are SEM images and (F) is the histogram representation of size distribution of LNCs.

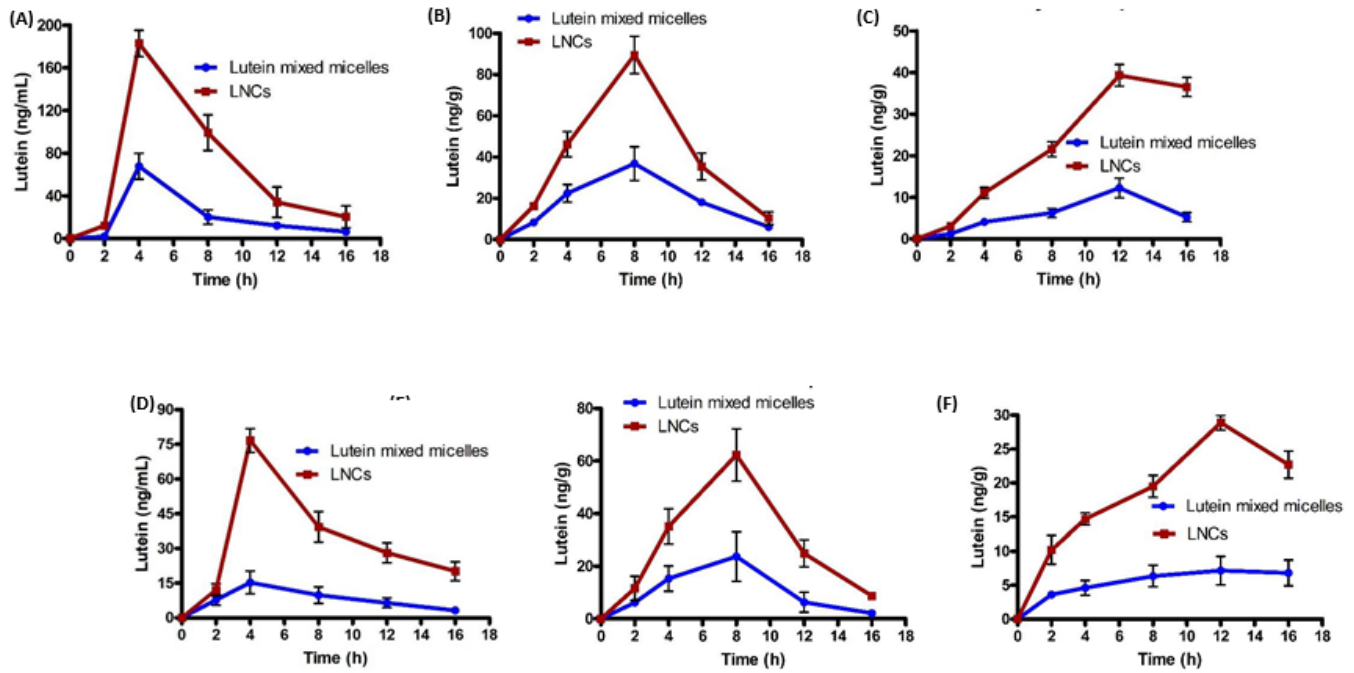

Figure 3

Pharmacokinetics of lutein from mixed micelles and LNCs (A) plasma (B) liver and (C) eye responses in control animal, (D) plasma (E) liver and (F) eye responses in diabetic rats. Data represented mean \pm SD (n=3).

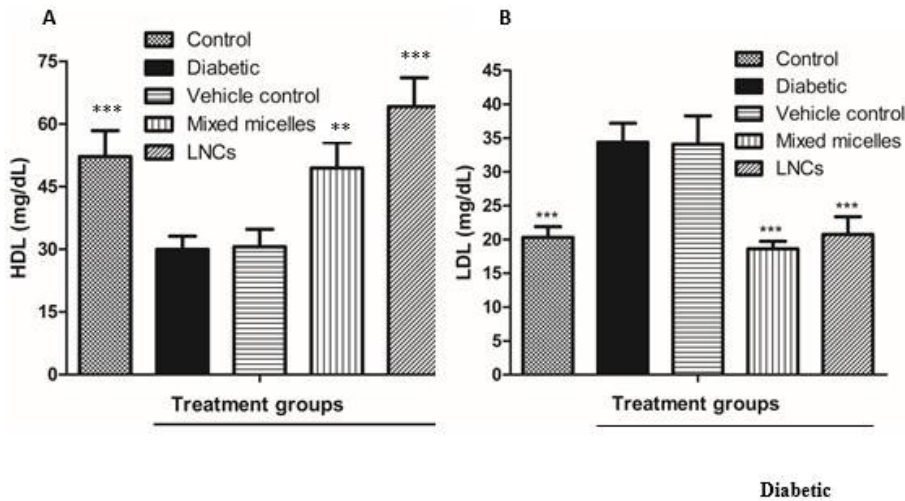

Figure 4

Plasma HDL (A) and LDL (B) levels in diabetic and LNCs treatment groups. Data are 506 expressed as means \pm SEM (n=3 per group). ANOVA followed by Tukey's test: ***P < 0.05 versus diabetic control; **P < 0.01 versus diabetic vehicle.

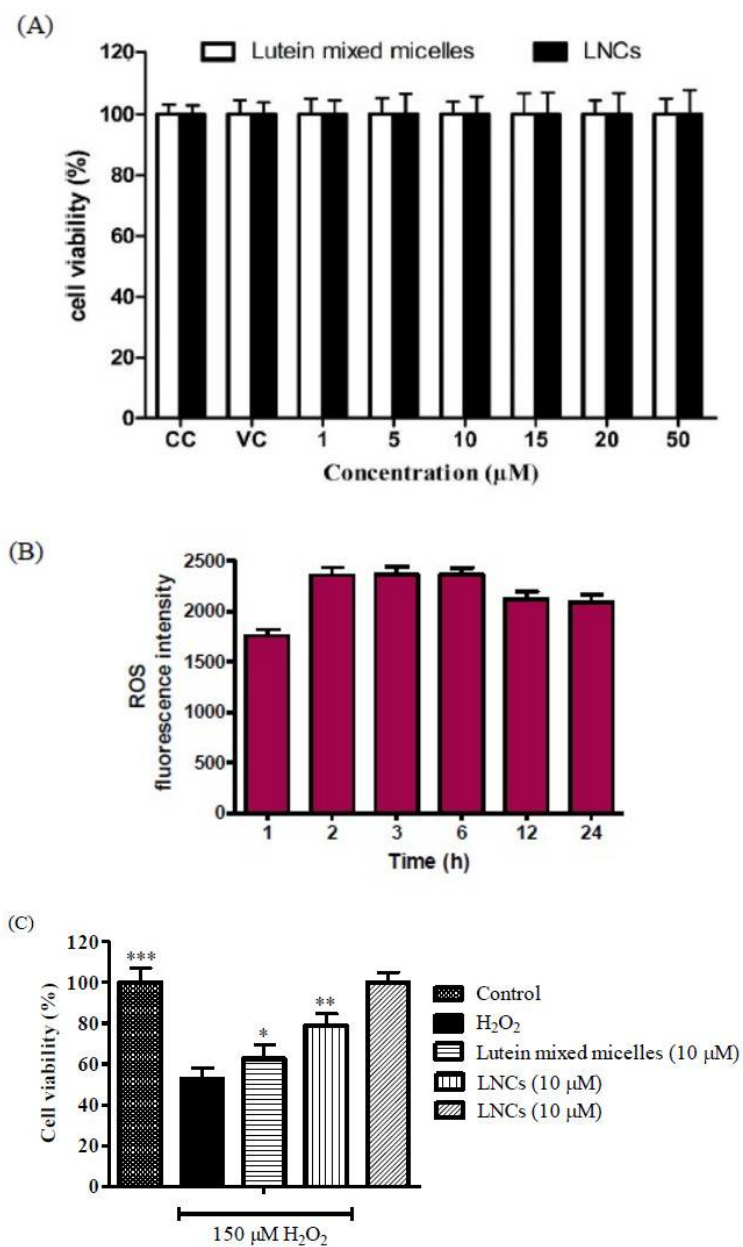

Figure 5

Cytotoxicity of LNCs and micellar lutein (A), H_2O_2 induced intracellular ROS at different time intervals (B) and cell viability under H_2O_2 induced oxidative stress with different treatments. Data are expressed as means \pm SEM (n=3 per group). ANOVA followed by Tukey's test: ***P < 0.05 versus H_2O_2 treatment; **P < 0.01 versus H_2O_2 treatment. CC = Cell control, VC = Vehicle control

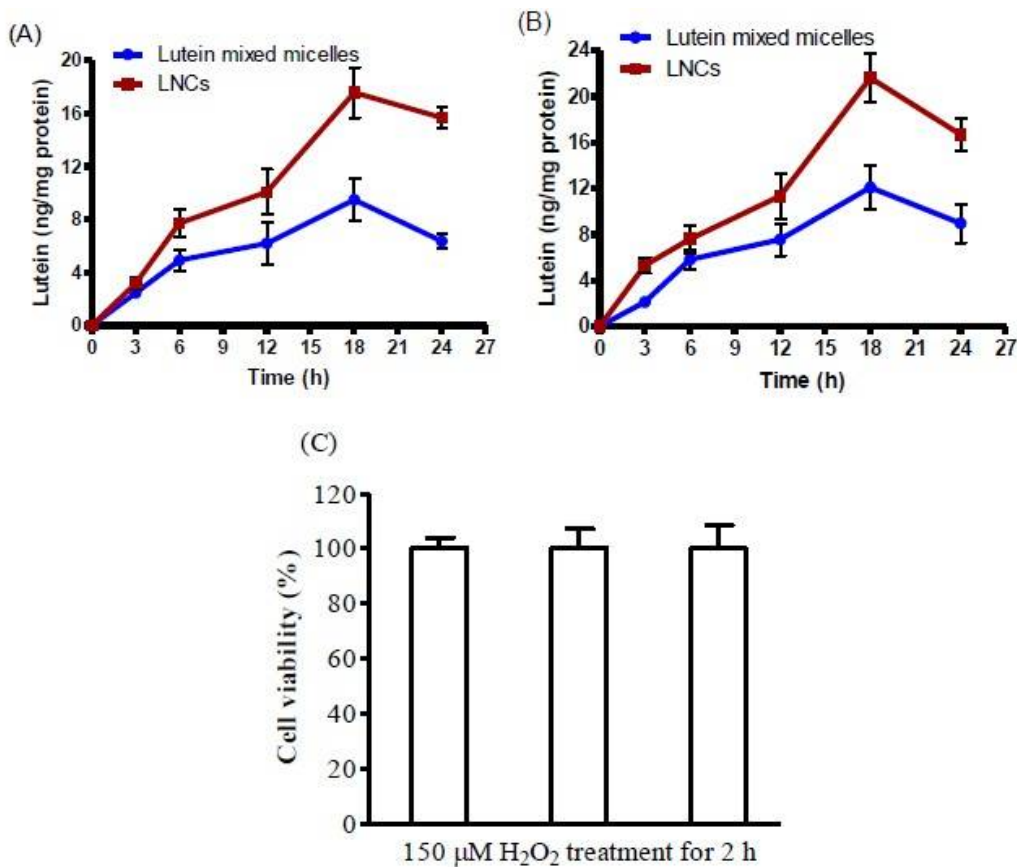

Figure 6

Lutein uptake from mixed micelles and LNCs in control (A) and H₂O₂ (150 μM for 2 h) induced OS (B) ARPE-19 cells and (C) ARPE-19 cell viability after H₂O₂ (150 μM for 2h) treatment. Data represented as mean ± SD (n=3).

Figure 7

LNCs attenuate the H₂O₂ induced intracellular ROS in ARPE-19 cells. Cells were treated with micellar lutein and LNCs (10 μM) for 18 h, followed by incubated with or without 150 μM of H₂O₂ for an additional 2 h. Intracellular ROS was determined by DCF-DA

dye. Data are expressed as mean \pm SEM (n=3 per group). ANOVA followed by Tukey's test: ***P < 0.05 versus H₂O₂ treatment; **P < 0.01 versus H₂O₂ treatment. CC = Cell control, VC = Vehicle control

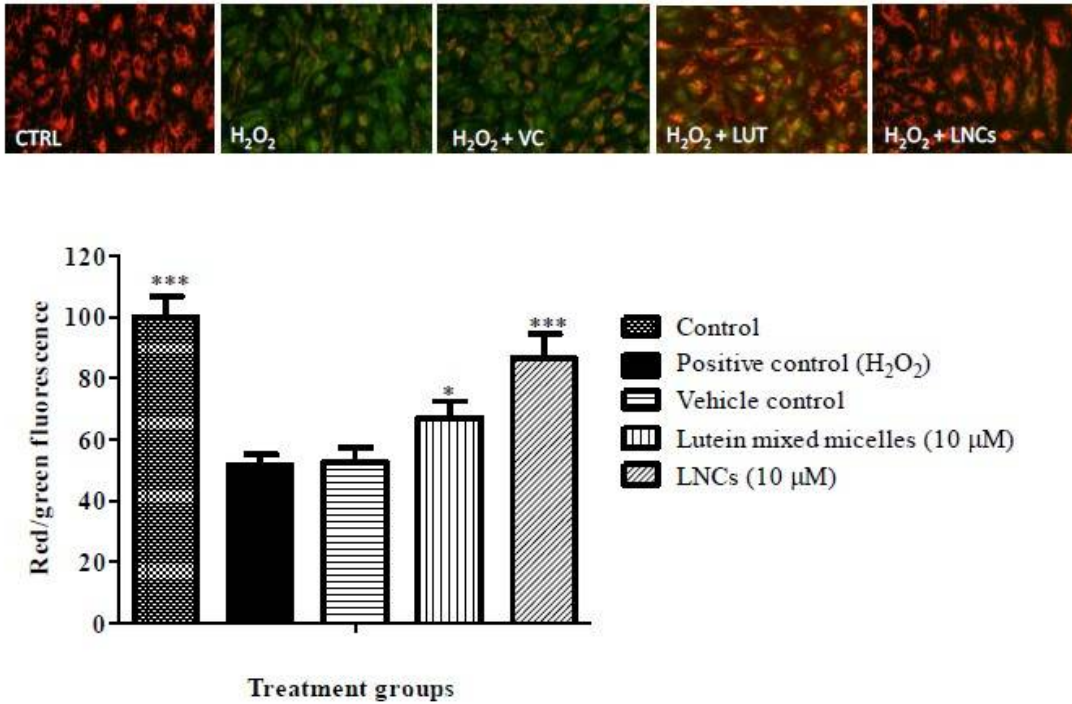

Figure 8

LNCs attenuated the loss of mitochondrial membrane potential ($\Delta\psi_m$) induced by H₂O₂ in ARPE-19 cells after pre-treatment with 10 μ M lutein either as mixed micelles or LNCs for 18 h. $\Delta\psi_m$ was determined by the JC-1 assay. Data are expressed as mean \pm SEM (n = 3 per group). ANOVA followed by Tukey's test: ***P < 0.05 versus H₂O₂ treatment; **P < 0.01 versus H₂O₂ treatment
