Abstract

Background: This study aimed to describe the clinical and imaging findings, including ultrasonography (US) findings, and long-term follow-up results in pediatric patients with localized cystic disease of the kidney (LCDK).

Methods: From January 2002 to August 2020, pediatric patients diagnosed with LCDK based on imaging findings showing multiple localized renal cysts with intervening normal renal parenchyma were retrospectively reviewed. Clinical presentations and US features of the affected and contralateral kidneys were reviewed and compared with computed tomography or magnetic resonance imaging findings, if available.

Results: A total of 18 patients (male:female = 11:7; median age, 8 years) were included. Initial clinical presentations were incidental findings (n = 5), abdominal pain (n = 5), or hematuria (n = 5). Of the seven (7/18, 39%) patients who showed multiple hyperechoic foci with ring-down artifacts within the cystic lesions on US, six patients showed focal calcification of the cysts on CT. Two (2/18, 11%) patients had tiny cysts in the contralateral kidney. During follow-up (range, 2–122 months), there was an increase in lesion size, with ipsilateral renal growth in four (4/18, 22%) patients. There was no renal function impairment at the initial presentation or during follow-up in all patients.

Conclusions: LCDK can present with tiny calcifications (39%), contralateral tiny renal cysts (11%), and mild size increase during renal growth (22%) in children without renal function impairment. Follow-up US is recommended without surgical intervention in these typical cases.

Background

Cystic disease of the kidney in the pediatric population is relatively rare and has a wide range of differential diagnoses. Localized cystic disease of the kidney (LCDK) is an uncommon, non-familial, and non-progressive kidney disorder that is not associated with cysts or malformations in other organs. It involves a part of the kidney (or rarely the entire kidney) with multiple cysts surrounded by normal renal parenchyma[1–3]. It is usually diagnosed in adults[2–4]. The differentiation of LCDK from other renal cystic diseases is important because LCDK is a benign condition and usually does not require any specific management or surgical intervention[5]. Therefore, it is important to easily and accurately diagnose LCDK and differentiate it from other cystic renal diseases.

The typical imaging finding of LCDK is a cluster of tightly spaced cysts of variable size within a single kidney with normal intervening parenchyma. Some cysts show internal calcification, and tiny one or two simple cysts are occasionally seen in the contralateral kidney[2–4]. These findings are based on computed tomography (CT) features in the adult population.

There have been only 11 previously reported pediatric LCDK cases[5–13]. Since LCDK in the pediatric population is rare, more than 50% of these reported cases were misdiagnosed and underwent unnecessary surgical excision. Therefore, this study aimed to review ultrasonography (US) findings and longer-term follow-up results in pediatric patients with LCDK.

Methods

Our Institutional Review Board approved this study and waived the requirement for informed consent because of the retrospective nature of the study. From January 2002 to October 2020, we retrospectively reviewed patients who were under the age of 18 who had the following imaging findings indicative of LCDK—cluster of tightly spaced cysts of variable size within a single kidney, but otherwise normal renal parenchyma between the cyst and throughout the rest of the kidney[1–3, 11]. We excluded patients who showed a capsule around the cysts to differentiate cystic neoplasms[2]. In addition, we excluded patients with multiple cysts in the ipsilateral and contralateral kidneys or cysts in other organs such as the pancreas or the liver to exclude polycystic kidney disease[11]. US features of the affected and contralateral kidneys were reviewed and compared with computed tomography (CT) or magnetic resonance imaging (MRI) findings, if available in the medical records. The medical records of the patients were reviewed to evaluate data on age at presentation, sex, presence or absence of family history of renal disease, presenting symptoms, follow-up duration, presence of renal function abnormality based on blood urea nitrogen and blood creatinine levels, and types of intervention performed.

Results

Clinical features

In total, 18 patients were diagnosed with LCDK during the study period. Eleven patients were male, and seven patients were female, with an age range of 3–16 years (median, 8 years). The most common presentations were non-specific abdominal pain (n = 5), gross or microscopic hematuria (n = 5), or incidental lesion (n = 5). Urinary tract infection (n = 1), fever (n = 1), or nausea (n = 1) were less common presentations. None of the patients had a family history of renal disease.

Based on imaging findings, conservative management with follow-up was performed in most cases, except in one patient who underwent partial nephrectomy for a suspected renal tumor. The follow-up duration was 2–122 months (median, 37.5 months). No renal complication or renal
function impairment was identified in any patient during follow-up.

Radiological Findings

US was performed in all patients. CT findings were available in nine patients, and MRI findings were available in six patients. Eleven patients had LCDK in the right kidney, and seven patients had LCDK in the left kidney. LCDK had no significant location predilection (Table 1). In all patients, US findings were characterized by multiple variable-sized, conglomerated, round cystic lesions with intervening normal renal parenchyma without a definite capsule and preserved cortical rim. The lesions showed no predisposition to the renal cortex or the renal medulla. Each cyst was round or oval with variable size. The cysts were relatively well defined by thin walls and had a sharp interface with the adjacent renal parenchyma, as previously described[2, 3].

M, male; F, female

Seven (7/18, 39%) patients showed multiple hyperechoic foci with ring-down artifacts within the normal intervening parenchyma at the cystic lesion on US (Fig. 1), including one patient who developed hyperechoic foci during follow-up (Fig. 2). Of these seven patients, six patients showed focal calcifications within the cyst walls on CT. There were no definite hyperattenuating cysts on precontrast CT. Two (2/18, 11%) patients had a tiny single cortical cyst in the contralateral kidney. No cystic lesions with intense wall enhancement or mural nodules were identified on either CT or MRI.

During follow-up, the cystic lesion size increased in four (4/18, 22%) patients. The initial age at diagnosis in these four patients was 3, 4, 5 months and 8 years. The absolute lesion length had increased with a range of 6–20 mm during follow-up (35–122 months). However, it was not significant
when the ipsilateral renal growth (range 7–30 mm) was considered.

Pathology

For the patient who underwent partial nephrectomy for suspected renal neoplasm (Fig. 3), pathological findings were evaluated. On cross-section, the lesion revealed multilocular cysts of variable size lined by flattened epithelium. The cysts contained clear serous fluid with smooth walls and no evidence of tumor or papillary formation. There was intervening normal renal parenchyma in the septum.

Discussion

LCDK was first described in 1979 by Cho et al.[6] and the terminology was defined by Slywotzkey et al.[2]. Since then, many studies have documented this unique disease, mostly in the adult population. Only 11 pediatric cases have been documented thus far (Supplementary Table 1) [5–13]. Seven patients were male and four patients were female, with their age ranging from 1.5 months to 16 years. Due to the rarity of the disease, LCDK was not included in the international working group consensus statement for kidney cysts and cystic kidney disease in children[14].

In our study, LCDK was present in 18 pediatric patients with a mean age of 8 years (range, 3 months to 16 years). Six patients were diagnosed with LCDK less than one year of age. One patient underwent nephrectomy, and 17 patients were conservatively treated by US follow-up. This is the first study to report multiple cases of pediatric LCDK with long-term US follow-up. Lack of awareness of the disease may lead to misdiagnosis and mistreatment, including unnecessary nephrectomy, as in previously reported pediatric cases[5–13]. Of the 11 pediatric reported cases, seven cases underwent surgical excision[5, 6, 8, 10, 12, 13, 15]. Among these seven cases, one patient underwent preoperative chemotherapy before nephrectomy because the radiologist suspected a malignant lesion[13]. Four cases were managed conservatively, and follow-up data were available in two cases. One case showed no interval change after seven years[7] and after one year[9].

In our study, LCDK was incidentally found in 27.8% patients. Sixty percent of the patients who were incidentally diagnosed with LCDK were under the age of one year. Our cases and previously reported cases that were diagnosed in newborns and during infancy suggest that LCDK may develop during the pediatric period and could be found incidentally during adulthood. The incidental initial diagnosis in adulthood might be possible because LCDK is non-progressive and there is no loss of renal function in the involved patients[2, 3].

The most common modality used in the evaluation of LCDK has been CT, and the disease has characteristic findings: multiple conglomerated simple cysts with normal intervening renal parenchyma[2, 3, 11]. US have also typically been used as the primary imaging tool in previous reports but the role has been underestimated. This might be because most previous studies have been in the adult population. In our study, similar characteristic findings of LCDK were also seen on US. Moreover, seven (38.8%) patients showed multiple hyperechoic foci with ring-down artifacts at intervening normal parenchyma within the cystic lesions on US. Six of seven patients showed focal calcification within the cyst walls on the corresponding CT. One patient developed hyperechoic foci during follow-up; however, the corresponding CT was not available in this patient. This finding is consistent with that of previous studies in the adult population, which demonstrated scattered calcification in cyst walls in 22–42% of the reported LCDK cases on CT[2, 3]. This is a discriminating point from other cystic masses, such as multilocular cystic nephroma, since calcification is rare[16]. The hyperechoic foci observed on US are similar to the previously noted lesions in autosomal recessive polycystic kidney disease (ARPKD)[17]. Urine stagnation in dilated tubules, which is a consequence of calcium precipitation, decreases excretion of urinary citrate, and alkaline urine has been suggested to be a possible mechanism for calcification in patients with ARPKD[18]. However, there is a lack of evidence on the pathological correlation to confirm these findings in LCDK, but the appearance and ring-down artifacts suggest the precipitation of some crystalline material, perhaps calcium compounds, in the normal intervening renal parenchyma. Ding et al. pathologically confirmed that cystic septa contain tubules and glomeruli and that the cystic spaces of LCDK were continuous with the dilated collecting ducts in some cases. Lymphocyte infiltrates, foamy histiocyte aggregates, and refractile crystals were occasionally identified in the cystic spaces of LCDK[1].

LCDK may resemble autosomal dominant polycystic kidney disease (ADPKD), but there are important points of discrimination. LCDK is unilateral and almost always involves only a part of the affected kidney, and coexistence of cystic lesions in other organs such as the liver or pancreas is uncommon[1–3, 11]. ADPKD can affect one kidney before contralateral renal cysts are visualized on imaging studies, mimicking unilateral renal involvement, especially in younger patients[19]. Since the gene for ADPKD has been identified in more than 90% of the patients, genetic evaluation is useful for differential diagnosis[20, 21]. However, in our study, genetic evaluation was not performed in all patients. Two patients showed tiny, simple cysts in the contralateral kidney. There were no cysts in other organs in these patients. Simple cysts in the contralateral kidney have also been reported in the LCDK patients in adult population[2, 3, 22]. In our study, there were six patients who were under one year who had characteristic US findings of LCDK. There may be concerns about the early manifestation of ADPKD in these infant patients. However, only one patient developed a tiny simple cyst in the contralateral kidney during follow-up. Imaging of the family members in the aforementioned patient did not reveal any cysts in the major organs. Renal function was within the normal range during the 56-month follow-up in this patient.

Previously reported LCDK studies have focused on CT and MRI findings because most of the case studies included adult patients. Establishing US findings of LCDK are very important in the pediatric population since US is a radiation- and sedation-free tool that can be easily be used for diagnosis and follow-up examination. From our experience, LCDK is a very stable and benign disease entity, but it requires follow-up imaging to
monitor potential interval size changes, as four patients in our study had an interval size increase during follow-up. However, considering the interval growth increase of the normal kidney during pediatric development, the finding was not significant. Establishing US findings of LCDK may help reduce unnecessary additional CT and MRI in pediatric patients. If cystic lesions with typical features of LCDK are noted on US, follow-up US is recommended in the pediatric population.

This study has some limitations. First, the study included a small number of patients and there was only one pathologically proven case. Second, we did not perform genetic studies related to renal cystic disease in all patients. Imaging of family members was performed in only one patient. However, there was no renal insufficiency or cyst in other organs in any patients. Third, since the follow-up duration was relatively long, hyperechoic foci in LCDK might have been more conspicuous due to technological improvement. However, this report describes a noteworthy number of pediatric LCDK cases, and long-term patient follow-up by imaging enhances the clinical significance of this study.

Conclusions

LCDK can be diagnosed when multifocal conglomerated cystic lesions with intervening normal renal parenchyma in one kidney are identified on US. LCDK can present with tiny calcifications (39%), contralateral tiny renal cysts (11%), and mild size increase during renal growth (22%) in children without renal function impairment. Follow-up US is recommended without surgical intervention in these typical cases.

Declarations

Ethics approval and consent to participate

- Following the Declaration of Helsinki, the study was approved as a retrospective human study by the Institutional Review Board of Severance Hospital (4-2019-0522). The informed consent of patient, parents, or guardians was waived. All methods were carried out in accordance with relevant guidelines and regulations.

Consent for publication: not applicable

Availability of data and materials

- All data generated or analysed during this study are included in this published article and its supplementary information files

Competing interests: The authors have no competing interest to declare.

Funding: not applicable

Authors’ contributions:

HY, MJK: study concept and design, data acquisition, data analysis and interpretation, and writing of manuscript. HY, MJK, HJS, MJL: data analysis, interpretation and revision of manuscript for important intellectual content. All authors read and approved the final manuscript.
