40 Abstract

41 Automatic pattern recognition using deep learning techniques has become increasingly
42 important. Unfortunately, due to limited system memory, general preprocessing methods
43 for high-resolution images in the spatial domain can lose important data information such
44 as high-frequency information and the region of interest. To overcome these limitations,
45 we propose an image segmentation approach in the compressed domain based on principal
46 component analysis (PCA) and discrete wavelet transform (DWT). After inference for
47 each tile using neural networks, a whole prediction image was reconstructed by wavelet
48 weighted ensemble (WWE) based on inverse discrete wavelet transform (IDWT). The
49 training and validation were performed using 351 colorectal biopsy specimens, which
50 were pathologically confirmed by two pathologists. For 39 test datasets, the average Dice
51 score was 0.852 ± 0.086 and the pixel accuracy was 0.962 ± 0.027. We can train the
52 networks for the high-resolution image (magnification x20) compared to the result in the
53 spatial domain (magnification x10) in same the region of interest ($6.25 \times 10^{-2} \ \mu m^2$).
54 The average Dice score and pixel accuracy are significantly increased by 6.4 % and 1.6 %,
55 respectively. We believe that our approach has great potential for accurate diagnosis in
56 pathology.

57

58 **MAIN TEXT**

59 **Introduction**

60 The large number of inspections for pathologists is exposed to the risk of misdiagnosis.
61 This leads to a rapid increase in medical expenses, an increase in the false diagnosis rate, a
62 decrease in medical productivity, and the risk of a cancer diagnosis. Automatic analyses of
63 pathological images can mitigate human effort, save time, and provide a confident
64 foundation for surgery and treatment. Convolutional neural networks (CNNs) are
65 especially popular for the automatic diagnosis of many diseases in pathology [1–13].
66 However, despite the continued increase in the speed and memory capacity of central
67 processing units (CPUs) and graphical processing units (GPUs), technological advances in
68 pathological image analysis are still hampered by large image sizes [14].

69 For high-resolution and large scale images, a general preprocessing method to relieve
70 memory limitation can induce important information loss. Several methods have been
71 explored to reduce image sizes, such as decimation, cropping, and compression [15–17].
72 Decimation is the major process for down sampling large images, and it can also reduce
73 noise power and improve signal-to-noise ratios (SNRs), thanks to an anti-aliasing filter.
74 However, decimation can cause a loss of high-frequency information, resulting in low
75 resolution due to the reduced signal bandwidth [18,19]. As another widely used method,
76 cropping extracts the wanted areas from whole slide images (WSIs) into tiles. Although no
77 information is missed with respect to a single tile, the spatial relationships between tiles
78 may be lose, which is critical because object judgments depend on the relative size and
79 color of each cell in the pathological image.

80 Compression is widely used both to minimize the size of an image file without
81 degradation in the image quality and to reduce irrelevance and redundancy of data in the
82 image. Thus, compression is mostly preferred to process large-scale images. For example,
83 detecting ships in satellite images is difficult due to their high resolution and
84 correspondingly large data volume. A compression technique called discrete wavelet
85 transform (DWT) resolves the difficulty in high-resolution ship detection and performs
86 better than conventional computer vision algorithms [20]. In addition, DWT is also useful for
87 texture classification, because its finite duration provides both the frequency and spatial
88 locality. In pathology, DWT analysis has been applied to classify tumors by using texture
89 analysis [21].

90 In this work, we propose a pathological image segmentation method in the compressed
91 domain. To compress large pathological images, we utilized not only DWT but also
92 principal component analysis (PCA) according to hematoxylin and eosin (H&E) staining
93 characteristics to reduce 3-channel RGB data to one channel [22]. We tested this inference
94 method in the compressed domain on colorectal cancer pathologic images from the
95 Catholic University of Korea Yeouido St. Mary's Hospital.

96 Our results imply that the method using the compressed domain is more useful for
97 pathologic segmentation than the method using the spatial domain, for three reasons: 1) The
98 average Dice score and pixel accuracy are significantly improved, by 6.4% and 1.6%,
99 respectively. 2) Using DWT, neural networks can be trained not only by spatial information
100 but also by texture information. 3) The performance can be more robust because of the large
101 ROI in training after compression; the size of the input image is reduced by 8%. This new
102 segmentation technique in the compressed domain can be potentially useful in applications
103 where large scale data and texture information are important, such as remote sensing [23] and
104 microscopy [24].

105 **Results**

106 **Data Distribution**

107 We used 390 WSIs of colorectal biopsy specimens. The average size of WSIs was 43,443
108 by 28,645 pixels. We split the dataset into three groups: 274 train data, 77 validation data,
109 and 39 test data (Supplementary Table I). We used this dataset to implement a pipeline to
110 achieve binary segmentation of normal and abnormal areas in colorectal cancer (CRC)
111 tissue images.

112 **Overall Result according to Each Method**

113 Table I compares the average Dice and Acc according to each method. As it shows, for the
114 model using compressed data, the average Dice and Acc results for the LL sub-band
115 increased by 5.6 % and 1.6 %, respectively, compared to those of the model in spatial
116 domain. The reason why LL's results improve is the impact of PCA. Channels are reduced
117 and background is removed, reducing input complexity and improving performance.
118 However, the average Dice and Acc results of the LH (-7.6 % for Dice and -2.5% for Acc),
119 HL (-4.0% for Dice and -2.2% for Acc), and HH (-6.4% for Dice and -1.5% for Acc) sub-
120 bands carrying high-frequency information decreased compared to those before
121 compression.

122 **The Trend for Dice and Acc according to Each Class**

123 Fig. 1 shows distribution Dice and Acc according to all classes. In the case of all tumor
124 classes, the average results for the LL sub-band are relatively high. Further, the average
125 results of the LH, HL, HH sub-bands carrying high-frequency components are relatively
126 high in ADENOCA and TAH (Fig. 1), which are relatively easy to detect due to advanced
127 disease progression and consequent pathological modifications. However, the results of the
128 LH, HL, HH sub-bands are less predictive for TAL, CARCINOID, and HYPERP (Fig. 1).
129 TAL (relatively less advanced), CARCINOID (malignant tumors but occurring in the
130 submucosa), and HYPERP (benign tumors) are difficult to accurately predict with only
131 high-frequency components. Based on these results, we propose an ensemble method that
132 can improve the results using both low-frequency and high-frequency information. In the

case of WAE, a widely used ensemble method, even though the weight is given to the result of the LL sub-band, the average Dice and Acc are lower than those of the result of the LL sub-band (-5.7% for Dice and -2.3 % for Acc). Compared to the no compression results, ADENOCA and TAH show good performance after WAE because the Dice and Acc in the high-frequency sub-bands such as LH, HL, and HH sub-band are higher than these of the no compression case (ADENOCA: +4.9% for Dice, +0.0% for Acc; TAH: +3.7% for Dice, +0.2% for Acc). However, in TAL, CARCINOID, and HYEPERP, which show low performance in the high-frequency sub-bands, the Dice and Acc after WAE are lower than those of no compression (TAL: +0.2% for Dice, -0.4% for Acc; CARCINOID: +4.3% for Dice, +2.3% for Acc; HYPERP: +11.1% for Dice, +4.1% for Acc;). On the other hand, after WWE, the average Dice and Acc increase by about 0.6% and 0.2%, respectively, compared to LL. For each class, the results of ADENOCA (+0.4% for Dice and +0.1% for Acc), TAH (+0.7% for Dice and +0.2% for Acc), TAL (+0.5% for Dice and +0.1% for Acc), CARCINOID (+1.5% for Dice and +0.1% for Acc), and HYPER (+0.8% for Dice and +1.8%for Acc) gradually increase. In particular, unlike WAE, the WWE also shows high predictive results for TAL (+9.2 % for Dice and +1.6% for Acc), CARCINOID (+8.7% for Dice and +3.7% for Acc), and HYPERP (+14% for Dice and +4.9% for Acc), and each shows higher performance than WAE.

Change in Dice in All Classes according to Low- (W_1) and High-frequency Weight (W_2, W_3, and W_4)

We checked change of Dice score in all classes according to low-frequency weight (W_1) and high-frequency weight (W_2, W_3, and W_4) to optimize each weight by conducting the empirical test. The best weights in the WWE are determined by the average Dice scores, as shown in Supplementary Table II. Fig 2 describes the change in Dice score with respect to various low-frequency weights (W_1) in all tumor classes (ADENOCA, TAH, TAL, CARCINOID, and HYPERP). From 0.6 to 0.9, the Dice scores of all the classes increase relatively steeply. Particularly, the increasing rates in the Dice scores of HYPERP and ADENOCA are relatively high. Beyond the W_1 value of 1.2, the Dice scores start being saturated in all classes. Further, we changed the values of the high-frequency weights (W_2, W_3, and W_4), but the changes in Dice scores are negligible as shown in Supplementary Fig 1.

Comparison of the Heat Map and Line Profiles between Annotation, the Result in the Spatial Domain, WAE, and WWE

Using a heat map and line profiles for tumor probability, we compared the segmentation prediction for annotation, the result in spatial domain, WAE, and WWE (Figs. 3a–d). The color bar indicates the tumor probability for each pixel. The heat map is overlaid on the original histology image, and a magnified image of the area in the colored border is located on top of the main image. The line profiles of the tumor probability cut along the red dotted dashed lines are located below the main image. Fig. 3(a) is the ground truth, annotated by a

172   pathologist. The pixel value in the annotation is 1, and the value in the other regions is 0.
173   Fig. 3(b) shows the segmentation result in spatial domain. There is a slight loss of high-
174   frequency information after decimation for efficient training, but the ROI used in single
175   training is the same as for the other methods. The magnified image in Fig. 3(b) predicts a
176   broader region than in the annotation, and the tumor probability in each pixel is relatively
177   low. The segmentation result for WAE, shown in Fig. 3(c), clearly is qualitatively better
178   than that in spatial domain. The final segmentation result with WWE has accurate edges as
179   well as a high probability in each pixel, compared to the other methods. The tumor
180   probability line profile processed with WWE is most similar to the original annotation
181   profile, proving the accuracy of our method.

182 **Average Dice for Each Method according to the Threshold**

183   The Dice scores for WWE for the wavelet sub-bands, WAE for the wavelet sub-bands, and
184   the result in spatial domain are compared across a range of threshold tumor probability
185   values (Fig. 4). Between threshold values of 0.1 and 0.4, the Dice score of the result in
186   spatial domain is slightly higher than that of WAE. However, beyond a threshold of 0.5, the
187   Dice score for this method drops sharply, compared to those of the other methods. WAE
188   and WWE continue perform robustly for all thresholds, and the Dice score of WWE is
189   consistently higher than that of WAE, thanks to the high-frequency information.

190 **Final Prediction Result of Five Different Tumor Classes using WWE**

191   Finally, we compared our WWE predicted image with the image annotated by a pathologist.
192   Fig. 5a-e shows tissue histology images from five different tumor categories. The
193   pathologist's annotations are shown in Fig. 5f-j. The corresponding predicted probability
194   map using WWE are shown in Fig. 5k-o and final overlaid tissue images are shown in Fig.
195   5p-t. The proposed WWE method generally segmented an afflicted area that corresponded
196   well to the ground truth images. The average Dice and Acc of the WWE are 0.852 ± 0.086
197   and 0.962 ± 0.027, respectively. The best Dice (0.887 ± 0.101) is achieved in TAH, where
198   the high-frequency information is important. On the other hand, the worst Dice ($0.830 \pm$
199   0.057) is in TAL, where the low-frequency information is important. As shown in the yellow
200   dotted boxes in the case of HYPERP (Figs. 5o, t), we often observed that the normal region
201   where dead nuclei are gathered is abnormally predicted. Possibly, these abnormal
202   predictions are caused by artifacts, such as tissue folds, ink, dust, and air bubbles, and further
203   artifact removal may be required. Despite these abnormalities, the overall prediction of
204   colorectal cancer using WWE was not biased to any one class: it performed well for all.

205 **Discussion**

206   The goal of this study is to increase diagnostic accuracy (e.g., Dice, Acc) by using a
207   compressed domain to reduce high-frequency information loss. The compressed domain
208   approach was employed in previous studies [20,25,26] showing good performance in

209   pathology classification not segmentation because there was no appropriate ensemble
210   method for results for each sub-band (e.g. LL, LH, HL, HH sub-bands results) [21,27–30]. In
211   this paper, we proposed the WWE method, which learns each low-frequency component
212   and high-frequency component in the compression domain and then combines them. With
213   the NVIDIA TITAN X 12Gb GPU used in this experiment, the U‑net++ model can be
214   trained on a maximum tile size of 512 by 512 at once. Therefore, in order to learn our
215   experimental ROI size of $0.625 \times 10^{-1} \ \mu m^{2}$ without compression, the resolution of the
216   original image (×20 magnification) would have to be lowered (×10 magnification) (Table
217   II). In this process, the loss of high-frequency components cannot be avoided. On the other
218   hand, our proposed method can handle a tile size of 1024 by 1024 before compression.
219   Thus, it is not necessary to lower the resolution to learn the same ROI size, and learning is
220   possible with ×20 magnification. In addition, compared to the result in spatial domain, our
221   proposed method can learn a tile that is four times larger than the limit of the hardware.
222   However, our method requires four times more the number of GPUs (Table II) at the same
223   time. From the perspective of time resources, in the case of a general CNN based on 2D
224   convolution, the amount of computation increases exponentially as the input size
225   increases. Therefore, it is faster to learn by separating one image into four images than to
226   learn an image that is 4 times larger at a single time. This case is similar to the principle of
227   the Cooley–Tukey FFT algorithm [31,32], and we believe that subsequent studies will also
228   meaningfully to reduce time consuming.

229   We have conducted a study to prevent the loss of high-frequency information that occurs
230   in the process of having to resize the image due to the limitation of the hardware and to
231   increase the accuracy of the final result by using protected high-frequency information.
232   Using a wavelet-weighted ensemble method, we found that accuracy was improved over
233   that of images in spatial domain. The overall accuracy was determined by the low-
234   frequency component, and the high-frequency component affected the margin. The
235   disadvantage is that it requires a relatively large amount of GPU resources. However, we
236   expect to reduce time-consuming compared to the result in spatial domain when the same
237   as the initial tile size. To the best of our knowledge, this is the first study to do WWE in
238   the compressed domain. We applied this processing method to colorectal cancer pathology
239   images, and we believe that it can also be applied in general pathology images and show a
240   similar increase in accuracy. Our proposed wavelet-weighted ensemble method can also
241   be applied in other fields that process large-scale images (e.g., astronomy and satellite
242   imagery) and that is important to margin (e.g., radiation therapy).

243 **Methods**

244   **Data preparation**

245   This study was reviewed and approved by the Institutional Review Board of the Catholic
246   University of Korea College of Medicine (SC18RNSI0116). All experiments were
247   conducted in accordance with relevant guidelines/regulations in the Catholic University of

248 Korea College of Medicine. Informed consent prior to the surgical procedures, all patients
249 had given their informed consent to use tissue samples and pathological diagnostic reports
250 for research purposes. We used a dataset using H&E stained-WSIs of colorectal biopsy
251 specimens at the Yeouido St. Mary's Hospital. The WSIs were ×20 magnified images taken
252 using a digital whole-slide camera (Aperio AT2, Leica biosystems, USA). The Whole slide
253 images (WSIs) were manually annotated by the three trained pathologists supervised by the
254 expert and performed routine histopathological examination by drawing the region of
255 interest in the slides that corresponded to one of the five labels: adenocarcinoma
256 (ADENOCA), high-grade adenoma with dysplasia (TAH), and low-grade adenoma with
257 dysplasia (TAL), carcinoid (CARCINOID), and hyperplastic polyp (HYPERP). The
258 average annotation time per WSI took 5-10 minutes. Next, annotations carried out by the
259 trained pathologists were reviewed by the three senior pathologists and if necessary then
260 modified and verified with the final checking verification by the one senior professors.
261 Cases that had discrepancies in the annotation labels resolved the issue through further
262 discussions. The images were excluded, when it was not possible to reach a consensus on a
263 lesion type for an image. Most of the WSI contained multiple annotation labels. Therefore,
264 a single WSI label of major diagnosis was assigned to a given WSI.

265 **Compressed image analysis**

266 In this study, we applied a compressed domain based on the wavelet transform used in
267 JPEG2000 for the segmentation of pathologic images. The pipeline is as follows: tile
268 extraction, z-axis compression, training and prediction in the compressed-domain using
269 CNNs, prediction from one tile to the whole image, and wavelet-weighted ensemble (WWE)
270 (Fig. 6). Each process is detailed in the following subsections.

271 **Tile extraction based on a sliding window algorithm (Figs. 6(a) and Supplementary**
272 **Fig. 2)**

273 When the tiles are extracted from one WSI, the information about location and adjacent tiles
274 is lost due to the limited fields-of-view. However, morphological information between
275 adjacent areas is crucial for diagnostic decisions. Two typical tile extraction methods, the
276 multiple ROI and sliding window methods, have been widely used to overcome this problem
277 [12]. Although the multiple ROI method is faster than the sliding window because of its low
278 redundancy, the sliding window method has the following advantages. First, the redundancy
279 in the sliding window method assists data augmentation, an essential pre-processing step in
280 a deep learning approach. Second, this method can overcome the limited field-of-view
281 problem indirectly because the overlapping area depends on adjacent tiles. Finally, the
282 overall accuracy can increase because the probability in the overlapping area is averaged
283 during summation from the tile to the whole image. In this work, we choose the sliding
284 window manner as the tile extraction method. Although the receptable maximum tile size
285 is 512×512 pixels due to the limitation of our GPU memory size, we extracted a tile that

286 is 1,024 × 1,024 pixels in size before the compression step. The stride is set to 256 pixels,
287 horizontally and vertically.

288 **Z-axis compression based on principal component analysis (PCA)**

289 Pathologic images have three red (R), green (G), and blue (B) channels (Fig. 7(a)). The
290 correlation is high among each color (Fig. 7(c)). Color variation in the pathologic image is
291 given by H&E staining, which dyes the cell nuclei blue, and dyes the extracellular matrix
292 and cytoplasm pink. Therefore, z-axis compression was applied only to the R and B
293 channels in the tissue region. First, Otsu algorithm were applied to extract the RGB values
294 at tissue region, and then the G values were removed [33]. PCA was applied to maximize the
295 variation between the R and B values and to minimize the mean squared error (Figs. 7(d))
296 [22]. This process reduces the image dimensionality and results in background reduction,
297 widely used in histopathology (Fig. 7(b)). The PCA algorithm is described in detail in
298 Supplementary Table III.

299 **Training neural networks in the compressed-domain (x- and y-axis compression)**

300 After the image depth compression (z-axis), discrete wavelet transform (DWT) was
301 performed on each tile to compress the information along the x- and y- axis [35]. Haar wavelet
302 is usually used to extract texture feature[28,30,36]. So, we decided 2D DWT based on Haar
303 wavelet and its sub-band was calculated using the following Equations (1) – (4):

$$W_\psi^A(j,m,n) = \frac{1}{\sqrt{MN}} \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} f(x,y)\psi_{j,m,n}^A,$$

304 (1)

$$W_\phi^V(j,m,n) = \frac{1}{\sqrt{MN}} \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} f(x,y)\phi_{j,m,n}^V,$$

305 (2)

$$W_\phi^H(j,m,n) = \frac{1}{\sqrt{MN}} \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} f(x,y)\phi_{j,m,n}^H,$$

306 (3)

$$W_\phi^D(j,m,n) = \frac{1}{\sqrt{MN}} \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} f(x,y)\phi_{j,m,n}^D,$$

307 (4)

308 where (x,y) is the coordinate of the input tile, (m,n) is the coordinate of the output sub-
309 band, $\psi_{j,m,n}^A(x,y)$ and $\phi_{j,m,n}^i(x,y)$ represent the 2D wavelet basis function of level j, W_ψ^A
310 describes an approximation of the original image called the LL (low-low) sub-band, and
311 W_ϕ^V, W_ϕ^H, and W_ϕ^D are high-frequency components whose directions are vertical, horizontal,
312 and diagonal. We call this transformed domain a compressed domain. [20]. These components
313 are called the LH (low-high) sub-band, HL (high-low) sub-band, and HH (high-high) sub-
314 band, respectively. Our proposed method using these compressed domain analyses has the
315 following benefits. First, the image size is reduced (e.g., from 1,024 × 1,024 pixels to 512

× 512 pixels), but all needed information is retained to perfectly reconstruct the original image. After reconstruction, the ROI can be increased without losing information, which is proportional to the generalization performance. Second, the method is useful for classifying texture because the result of the 2D grey-level co-occurrence matrix (GLCM) in the wavelet domain can capture texture information from the wavelet sub-band according to the cancer grading [28]. We input all four DWT sub-bands in parallel to each separate segmentation model, U-Net++ [37]. We used the DiceCE loss function combined the Dice coefficients and the cross- entropies [38]. Each sub-band model took two NVidia Titan X GPUs. The total batch size was six for each GPU.

Prediction from tiles to whole images using wavelet weighted ensemble (WWE)

The reconstruction process is described here. After producing a whole probability map for each sub-band, as shown in Fig. 6(e), we applied ensemble learning based on wavelet weighted ensemble (WWE) to four trained neural networks for each sub-band (Fig. 8). Initially, a binary mask image (Fig. 8(b)) is obtained from the original image by using an Otsu algorithm (Fig. 8(a)) [33]. After a 2D wavelet transform based on the Haar wavelet, four wavelet sub-bands for the binary tissue mask were generated (Fig. 8(c)). We defined them as the wavelet weights, namely the LL weight, LH weight, HL weight, and HH weight. We added a small value, ε, to each wavelet weight, then multiplied it by their assigned weights (Fig. 8(d)). Lastly, we multiplied the weights by the corresponding probability map (Fig. 8(e)), and then applied an inverse discrete wavelet transform that also used the Haar wavelet to obtain a final probability map and overlay image (Fig. 8f-g). Parameters such as W_1, W_2, W_3, and W_4 were empirically determined. Ideally, if the same region of each sub-band has a probability of 1, the reconstruction probability of that region should also be 1 without those parameters. However, we gave the LL sub-band more weight (i.e., 1.8) because the LL sub-band has a basic characteristic of the original image. Then, ε was added to remove the zero terms. The ensemble method is expressed by the following Equation (5):

$$R_{WWE} = \frac{1}{\sqrt{MN}} \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} W_1 (Y_\psi^A + \varepsilon) R_A(m,n) \psi_{1,m,n}^A$$

$$+ \frac{1}{\sqrt{MN}} \sum_{i=H,V,D} \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} W_i (Y_\phi^i + \varepsilon) R_i(m,n) \varphi_{1,m,n}^i, \quad (5)$$

where $\psi_{1,m,n}^A(x,y)$ and $\phi_{1,m,n}^i(x,y)$ represent 2D wavelet basis functions of level 1, Y_ψ^A describes an approximation of the binary tissue mask (LL sub-band weight), and Y_ϕ^i are high-frequency components (LH, HL, and HH sub-band weights) for the binary tissue mask whose directions are horizontal, vertical, and diagonal, respectively. R_A and R_i describe the probability map for each sub-band. R_{WWE} is the final prediction result after wavelet weighted ensemble (WWE).

$$\underset{W \in \Re^4}{\arg\max} f_d(R_{WWE}(R_A, R_H, R_V, R_D; W)). \quad (6)$$

To optimize the weight parameters such as W_1, W_2, W_3, and W_4, we applied optimization that satisfied Equation (6), where $W = (W_1, W_2, W_3, W_4)$ and $f_d(x)$ is the function that decides the average Dice score of x. The range of each parameter is from 0.3 to 3.0, with a step size of 0.3. For comparison, Supplementary Table II shows the average Dice scores for W_1, W_2, W_3, and W_4. We chose the parameter values as $W_1 = 1.8$, $W_2 = 0.9$, $W_3 = 0.9$, and $W_4 = 0.3$.

Experimental setup

The qualities of the predictions were quantified by using the Dice score (Dice) and pixel accuracy (Acc), as follows:

$$Dice = \frac{2 \times N_{TP}}{2 \times N_{TP} + N_{FP} + N_{FN}}, \qquad (7)$$

$$Acc = \frac{N_{TP} + N_{TN}}{N_{TP} + N_{TN} + N_{FP} + N_{FN}}, \qquad (8)$$

where $N_{TP}, N_{TN}, N_{FP},$ and N_{FN} are the number of pixels for true-positive, false-positive, true-negative, and false-negative.

For the 39 WSIs test dataset, our proposed ensemble method (i.e., WWE) was compared with the model in three ways: (1) using the data after decimation and applying sliding window tile extraction instead of compression (Spatial domain, pixel size, 512 by 512 pixels; strides of sliding window, 128 pixels; x10 magnification), (2) using compressed data such as the LL, LH, HL, and HH sub-bands (Compressed domain), and (3) using the weighted average ensemble (WAE) for each sub-band result. The WAE is expressed as follows:

$$R_{WAE} = \frac{W_1 R_A + W_2 R_H + W_3 R_V + W_4 R_D}{W_1 + W_2 + W_3 + W_4}, \qquad (9)$$

where R_A, R_H, R_V, and R_D describe the probability maps for each sub-band, and R_{WAE} is the final prediction result after the weighted average ensemble. R_A , R_H, R_V, and R_D describe probability the maps for the LL, LH, HL, and HH sub-bands, respectively. We set the same weight values in WAE as those in WWE ($W_1 = 1.8$, $W_2 = 0.9$, $W_3 = 0.9$, and $W_4 = 0.3$).

In order to verify the excellence of the proposed method, we progressed experiments as follows: (1) To compare average Dice and Acc according to each method, (2) To observe distribution of Dice and Acc according to all classes, (3) Check dice change of all classes according to low-frequency weight (W_1) and high-frequency weight (W_2, W_3, and W_4), (4) To compare sample images and its line profiles according to each method, (5) To compare with Dice of WWE, WAE, and the result in spatial domain according to threshold for tumor probability.
