10 **Abstract**

11 Understanding inflow dynamics in a dam lake forms the basis for optimal dam operation

12 and management practices. However, methods pertaining to adequately determining

13 negative inflows and addressing them, as well as quantifying uncertainties in dam inflow,

14 have been scarcely investigated. In this study, the inflow was observed using two pairs of

15 fluvial acoustic tomography (FAT) systems placed diagonally in a dam lake, forming a

16 crossed-shaped pattern. The "travel-time" principle is the primary approach for

17 measuring the inflow by FAT. The novelty of this study is in discussing the inflow

18 characteristics within a slow water-flow environment monitored by FAT. Based on the

19 reciprocal sound transmission, we upgraded an equation to estimate the flow direction;

20 this newly proposed generalized equation can be used in a fluctuating flow environment.

21 We also discussed the sound propagation characteristics for slow flow velocities. Finally,

22 we demonstrated that a small inaccuracy in the acoustic signal, even by a sub-millisecond,

23 can cause significant errors in measurements. One of the novel findings of this study is

24 the detection of internal waves using the improved flow direction equation and acoustic

25 travel-time records. Overall, this study presents a promising approach for inflow

26 measurements under extremely slow flow conditions.

27

1. Introduction

Dams are important hydraulic structures because they have various positive impacts on the environment (Hariri-Ardebili 2018) through single or multi-purpose functions, including flood control, water supply, and hydroelectric power generation. However, dam construction is accompanied by the transformation of a wide range of aquatic ecosystems and alteration of river flow dynamics. Among the most prominent effects of dam construction are variations in sediment transport conditions, alteration of river thermal regime, obstruction of fish migratory patterns, and destabilization of riverine biodiversity (Allan 2004; Nazeer et al. 2016; Stähly et al. 2019). These effects may continue for many years, even decades, or constitute a permanent ecohydrological change that may or may not reach a new equilibrium. Hence, understanding the effects of a dam on upstream and downstream sites is a key challenge in ecohydrology (Gupta et al. 2012).

Accurate measurement of dam inflow is critical because it allows for optimal planning and management practices with respect to water resources, particularly for flood control and power generation. Control strategies for power generation vary for low and high inflow rates. Similarly, dam flush patterns are scheduled and calibrated based on the recorded amount of inflow, which differs during dry and rainy days (Ahmad and Hossain 2019). Accurate dam inflow forecasting has been a focal point in recent research studies (Ahmad and Hossain 2019; Hadiyan et al. 2020). The selection of suitable methods for accurate inflow forecasting and modeling considerably depends on watershed characteristics and available data. In this regard, accurate real-time and/or quasi real-time quantification of stream dynamics is a severe challenge encountered while improving the

52   performance of reservoir inflow forecasting, creating physical models of dam inflow, and,

53   more importantly, regulating the outflow quantities.

54   Typically, dam inflow is computed using the main water balance method represented by

55   the following equation:

56    $$Q_I = Q_O + \frac{\Delta S}{\Delta T} + Q_L \qquad (1)$$

57   where Q_I and Q_O are the reservoir inflow and outflow, respectively; ΔS ($\Delta S = S_{i+1} - S_i$)

58   is the difference between the final and initial water storage for the time period ΔT ($\Delta T =$

59    $T_{i+1} - T_i$); and Q_L is the amount of water loss from the reservoir, including that from

60   evaporation and seepage (Deng et al. 2015). The temporal variation in the reservoir

61   storage, S_i, is a function of the observed water level, H_i, and can be expressed as $S_i =$

62    $f(H_i)$. Nonetheless, uncertainties exist in the reservoir inflow derived by the main water

63   balance method as a result of errors in the reservoir stage-storage relationships and water

64   level measurements (Tao 1999). Stage-storage errors are generated by continuous

65   alteration in the topography of the reservoir lake due to continuous sediment deposition

66   mobilized from upstream regions and as a consequence of poor lake bed and terrain

67   surveying techniques. The limitations of water level monitoring techniques, along with

68   certain natural influencing factors, such as reservoir waves, induce errors in the water

69   level records (Deng et al. 2015).

70   Previous studies aimed to improve reservoir inflow measurements and minimize potential

71   errors in the inflow estimates using various approaches, such as the ensemble Kalman

72   filter (EnKF) (Deng et al. 2015), applying the moving average of mean water balance

73   equation (Budu 2014), and employing remote sensing information for reservoir slope

storage computation (Suzuki et al. 2008). These studies have led to improvements in the

accuracy of dam inflow quantification; however, additional efforts should be directed

toward improving the precision of reservoir inflow measurement techniques. Likewise,

certain issues related to dam inflow estimation, such as adopting methods to accurately

address and determine the negative inflows and quantify the uncertainties in dam inflow,

have received little attention.

In cases of considerably slow flow environments, such as inflow to a dam lake, measuring

variations in water stage and storage does not reflect sufficient precise information on

real-time inflow dynamics. Alternatively, to acquire an average stream cross-sectional

velocity and the corresponding flowrate, a set of one-point current meters can be installed.

However, this approach cannot be considered practical for long-term measurement in

sites such as dam lakes and may even be obstructed in certain locations due to site

utilization by fisheries or shipping traffic (Zhu et al. 2012).

This study presents findings from a site-based observation of the inflow to a dam lake

obtained using an advanced hydroacoustic tomography system; this study is based on

travel-time principles and discusses the prominent issues observed during our monitoring

program. We aim to answer the following research questions: 1) What kind of information

and knowledge can be derived using underwater acoustic tomography during the slow

flow of controlled reservoir releases? 2) What kind of hydrological processes can be

identified to improve and correct the analytical models for inflow estimation? Our main

objective was to identify the hydrological features that can be deduced from sound

transmission in water within slow flows, rather than developing advanced analytical

models to calculate the accurate inflow values.

97   The key contributions of this study are novel in different aspects. First, to the best of our

98   knowledge, in a scientific sense, cross-sectional average velocity and inflow

99   measurements in a shallow dam lake (by means of reciprocal sound transmission) have

100 not been investigated previously. In this study, we observed the temporal variations of

101 inflow dynamics using crossed acoustic path configurations executed by two pairs of

102 hydroacoustic tomographic systems with two distinct frequencies, which also offers a

103 technical novelty to our study. Moreover, we upgraded the determination of flow

104 direction proposed in a previous study by improving it to determine fluctuating flow

105 direction. The greatest advantages of hydroacoustics are its speed, functionality, and

106 accuracy in providing a detailed image, thereby facilitating a reliable understanding of

107 the hydrological processes that otherwise could not be identified by conventional means

108 of hydrological systems analysis.

109 The remainder of this paper is organized as follows. The study area of Haji Dam and

110 Yachiyo Lake and the methods used in our study are described in Section 2. The results

111 and discussion are presented in Sections 3 and 4, respectively. Finally, the main

112 conclusions are presented in Section 5.

113 **2.   Materials and methods**

114 *2.1. Study area*

115 Field observations were conducted in Haji Dam, a concrete gravity dam located in

116 Akitakata City, Hiroshima, Japan (Fig. 1). Haji Dam was built on the upstream region of

117 the Gōno River, which is the main river in Chūgoku area (Hiroshima, Okayama, Shimane,

118 Tottori, and Yamaguchi.). Its mainstream rises from the mountain region of the

119 Kitahiroshima city, runs through Hiroshima and Shimane prefectures, and finally,

120 discharges into the Sea of Japan near Gōtsu town in Shimane prefecture (Fig. 1a). The

121 climate of the dam region is generally warm and temperate. The mean annual temperature

122 is 11.7 °C, and the annual precipitation is approximately 1800 mm.

123 **Table 1.** Main specifications of Haji dam and its storage lake (Yachiyo Lake)

Haji Dam specifications	
Dam wall height	50 m
Dam wall top length	300 m
Dam mass	210,000 m^3
Catchment area	307.5 km^2
Yachiyo Lake area	2.8 km^2
Full reservoir storage capacity	47,300,000 m^3
Effective water storage capacity	41,100,000 m^3

124

125 Table 1 lists the main characteristics of Haji Dam. The dam serves multiple purposes,

126 including flood control (specifically during the East Asian rainy season), power

127 generation, water supply, and irrigation, in Hiroshima prefecture. The lake formed by

128 Haji Dam is called Yachiyo Lake. As seen in Fig. 1b, the dam lake is stomach-shaped,

129 thus being an ideal area to monitor slow inflow dynamics and study several hydrological

130 characteristics.

131 **Fig. 1** a) Location of the observation site; b) map showing Gōno River, Haji Dam, and

132 Yachiyo Lake; and c) study area map with inflow measurement zone and instrument

133 positions.

134 *2.2. Methods*

135 2.2.1. Inflow measurements using fluvial acoustic tomography (FAT) system

136 In this study, tomographic measurements of inflow at Yachiyo Lake were performed

137 using a fluvial acoustic tomography (FAT) system. Based on the travel-time approach,

138 the FAT system is capable of computing the cross-sectional average sound speed in water

139 (c) and flow velocity along the sound ray path (u). Travel time is the time it takes to

140 transmit an acoustic pulse from one transducer to the target transducer. Hence, for a pair

141 of transducers (such as S1 and S2; Fig. 1c), the recorded travel times, t_{S1} (i.e., the

142 transmitted acoustic signal from upstream transducer S1 to the corresponding

143 downstream transducer S2) and t_{S2} (i.e., the transmitted acoustic signal from the

144 downstream transducer S2 to the corresponding upstream transducer S1), are used to

145 estimate the cross-sectional average sound speed and velocity along the transmission line

146 (S1_S2) as follows:

147
$$c = \frac{D_S}{2}\left(\frac{1}{t_{S1}} + \frac{1}{t_{S2}}\right) \qquad (2)$$

148
$$u = \frac{D_S}{2}\left(\frac{1}{t_{S1}} - \frac{1}{t_{S2}}\right), \qquad (3)$$

149 where D_S is the oblique distance between transducers S1 and S2. Accordingly, the inflow

150 using FAT can be estimated as:

151
$$Q_{FAT} = u_S \times A_S \times \tan\theta_1 \qquad (4)$$

152 A_S is the cross-sectional area along transmission line S1_S2, and θ_1 is the angle between

153 transmission line S1_S2 and the inflow direction. Although several approaches can be

154 used to estimate the flow direction of the FAT system (Al Sawaf et al. 2020), we used

155 two crossed-path configuration approaches to estimate the flow direction.

A dam lake is an ideal area for analyzing sound transmission; however, to overcome obstacles encountered with sound propagation in water and attain precise data recording, the acoustic carrier signal is modulated using a maximum-length sequence (M-sequence), and the received signal is considered to be a set of multipath signals with the same arrival time. Hence, selecting the cross-correlation of the received signal with a replica of the transmitted signal is similar to sending a single strong pulse. The M-sequence is a type of pseudorandom signal, by which the phase shift of π in the carrier is produced at varying time intervals (Simon MK, Omura JK 1985).

The FAT system consists of a pair of processing units connected to underwater acoustic transducers. The main operation settings of the FAT systems used in this experiment are summarized in Table 2. In this study, two pairs of FAT systems were placed diagonally on the lake banks, forming a cross-shaped pattern, as shown in Fig. 1c. Figure 1c also shows the placements of the FAT transducers during the observation period. In this study, two different transmission frequencies were used to monitor the inflow dynamics, with different transmission rates. Along S1_S2, the transmission frequency was 53 kHz with a transmission rate of 10 s, whereas T1_T2 was accomplished using a 30 kHz transmission frequency at a transmission rate of 30 s, and both transducers served the dual function of transmitting and receiving acoustic signals.

At the beginning of the observation period, the water in the dam lake was deep; thus, all transducers were installed approximately 1.5 m below the water surface and suspended on floating boats. The floating boats were poised using nearby trees and/or rocks. At the end of each transducer, a counterweight was fixed to prevent the transducer from drifting in the event of unexpectedly high inflow velocities.

Table 2. Main operation settings of fluvial acoustic tomography systems

Station	Transmission frequency	Transducer type	Signal transmission rate	Length between stations	Expected arrival time* (milliseconds)
S1_S2	53 kHz	Omnidirectional broadband transducers (T226, Neptune Sonar Ltd)	Each 10 s	253.04 m	174.5 ms
T1_T2	30 kHz	Omnidirectional broadband transducers (T257, Neptune Sonar Ltd)	Each 30 s	287.50 m	198.2 ms

180 *Assuming that the sound speed in freshwater environment is 1450 m/s

181 There are several reasons for using two distinctive frequencies. First, a new generation of

182 the FAT system was developed in our laboratory; therefore, to assess the performance of

183 this version within slow inflow velocities, two central frequencies were tested. Second,

184 based on our experience with hydroacoustic tomography in rivers, we hypothesize that a

185 higher transmission frequency can perform outstandingly in cases of slow water velocity.

186 In addition, shorter acoustic paths (e.g., S1_S2) entail higher frequencies and vice versa.

187 Furthermore, we used a cross-shaped acoustic path to determine the continuous

188 measurements of the inflow direction (θ_1 and θ_2), as depicted in Fig. 2. This monitoring

189 pattern would be beneficial for tracking slow and fluctuating inflow directions and

190 detecting any period of negative inflows that could be encountered during the discrete

191 opening and closing of the dam gate. Additional details regarding the flow angle

192 estimation are provided in Section 2.2.2.

10

193   2.2.2.   Determination of the inflow direction acquired using cross-shaped acoustic path

194   configuration

195   Bahreinimotlagh et al. (2016) proposed the following equation for determining flow

196   direction:

197 $$Q_{S1S2} = Q_{T1T2}, \hspace{3cm} (5)$$

198 $$u_1 \times A_1 \times \tan\theta_1 = u_2 \times A_2 \times \tan\theta_2 \hspace{2cm} (6)$$

199   where Q_{S1S2}, u_1, and A_1 are the discharge, velocity, and cross-sectional area along S1_S2,

200   respectively; Q_{T1T2}, u_2, and A_2 are the discharge, velocity, and cross-sectional area along

201   T1_T2, respectively; and θ_2 is the angle between transmission line T1_T2 and the inflow

202   direction. As illustrated in Fig. 1c, $\emptyset_1 = \theta_1 + \theta_2$ is the angle formed by the transection

203   of the two acoustic paths; therefore, it is substituted in Eq. (6) as follows:

204 $$\theta_1 = \tan^{-1}\left(\frac{u_1 \times A_1}{u_2 \times A_2} \times \tan(\emptyset_1 - \theta_1)\right) \hspace{2cm} (7)$$

205   In essence, θ_1 requires an iteration-solving approach; therefore, using trigonometric

206   expansion, Eq. (7) can be explicitly expressed as follows:

207 $$\theta_1 = \cos^{-1}\left(\frac{1}{2}\sqrt{\frac{\sqrt{2}\cos(\emptyset_1)\sqrt{u_1{}^2 A_1{}^2 + \cos\frac{(2\emptyset_1)(u_1 A_1 - u_2 A_2)^2 + 6 A_1 A_2 u_1 u_2 + u_2{}^2 A_2{}^2 +}{\cos(2\emptyset_1)(u_2 A_2 - u_1 A_1) + 3u_1 A_1 + u_2 A_2}}}{u_1 A_1 + u_2 A_2}}\right) \hspace{0.5cm} (8)$$

208   Equation (8) is limited to unidirectional flow from upstream to downstream.

209   Consequently, to improve the equation representability, $\emptyset_1$ or $\emptyset_2$ must be carefully

210   selected based on the flow direction. This can be accomplished by considering the

211 difference between the arrival times of each pair of transducers and selecting proper

212 geometrical axes, as illustrated in Fig. 2. In the case of Fig. 2d, both velocities along

213 S1_S2 and T1_T2 were positive; therefore, according to Eq. (3), in this case $t_{S1} < t_{S2}$,

214 $t_{T1} < t_{T2}$ and $\emptyset_1 = \theta_1 + \theta_2$. Thus, the current direction can be inferred to be in the 4th

215 quadrant (Q4) of the x shape. Likewise, if $t_{S1} > t_{S2}$ and $t_{T1} > t_{T2}$, $\emptyset_1 = \theta_1 + \theta_2$, but in

216 this case, both velocities were negative (Fig. 2b), and the direction was in the 2nd quadrant

217 (Q2). However, if $t_{S1} > t_{S2}$ and $t_{T1} < t_{T2}$ (i.e., Q1) or $t_{S1} < t_{S2}$ and $t_{T1} > t_{T2}$ (Q3),

218 then $\emptyset_2 = \theta_1 + \theta_2$ (Figs. 2a, 2c).

219

220 **Fig. 2** Visualization of flow direction over proposed axes

221 according to recorded arrival times

222

223 *2.3. Auxiliary measurements*

224 The temporal variations in the mean water level and water temperature were acquired

225 every 5 min using a HOBO®_U20 level-temperature logger attached to the bridge

226 column (see "WL" Fig. 1c). The bed topography survey along the two cross-sections

227 (S1_S2 and T1_T2) was conducted using an autonomous boat equipped with GPS and a

228 single-beam echo sounder at a frequency of 200 kHz (resolution of 0.01 m). The time

229 series of the cross-sectional area along S1_S2 and T1_T2 were evaluated by computing

230 the integration between the riverbed and the time series of the average water level

231 observed by the water level logger.

232   Water temperature profiles were collected using CastAway [a conductivity-temperature-

233   depth (CTD) logger] at different locations in the lake (P1, P2, P3, and P4 in Fig. 1c) on

234   October 19, 2020 (fall) and December 2, 2020 (early winter).

235   Finally, the records of water level, storage, inflow, and outflow were provided by the Haji

236   Dam Monitoring Office (HDMO) and used for further analyses and comparisons. The

237   inflow at Haji Dam was measured using the main water balance approach, where the

238   water level was measured continuously every 10 min using a quartz-type water-level

239   gauge monitoring unit.

240   Our observation started on November 18, 2020 and ended on December 5, 2020. Owing

241   to certain difficulties related to site accessibility due to severe climate and the restrictions

242   influenced by the COVID-19 pandemic, certain tomographic records could not be

243   obtained before November 30, 2020. No rainfall was observed during the study period.

244   **3.   Results**

245   *3.1. Time series of water level, storage, and water temperature during the*

246   *observation period*

247   The temporal variation at the water stage, as measured by the HDMO, is plotted in Fig.

248   3a and was consistent with the readings obtained by the water level-temperature logger.

249   In general, both water level records are highly comparable to each other, even though the

250   HDMO dataset resolution was 10 min, while the water level logger was set to 5 min.

251   Figure 3a shows that the water stage at the dam lake exhibited a daily steady increment

252   estimated at 8 cm. Nonetheless, HDMO performs a scheduled water release for 5 h every

253   afternoon, resulting in approximately 0.5% storage reduction per day (Fig. 3b).

254   **Fig. 3** Time series plots of a) mean water level recorded by Haji Dam Monitoring

255   Office (HDMO; red) and water level-temperature sensor (black), b) temporal variation

256   of storage, and c) average water temperature. Releasing periods are shaded in blue

257

258   The water temperature recorded by the water level temperature logger is presented in Fig.

259   3c. Notably, water temperature was almost constant during the study period. As seen in

260   Fig. 3c, the water temperature during the observation period was ~12 ℃; however, on the

261   last day, the water temperature dropped drastically because water storage near the sensor

262   was low.

263   *3.2. Hydroacoustic measurements*

264   3.2.1.   Arrival time records

265   As depicted in Figs. 4a and b and Figs. 5a and b, samples of the stack plots for the cross-

266   correlation pattern signals were transmitted from the downstream transducer to the

267   upstream transducer and vice versa for S1_S2 and T1_T2, respectively. The diagrams are

268   shown at 5 min intervals and two main groups of arrival times, with a difference of

269   approximately 0.35 ms for the 53-kHz system. However, in the case of the 30-kHz system,

270   only one primary arrival group is observed, whereas multiple arrival peaks are evident in

271   Fig. 5b, with an approximate difference of 1 ms.

272   In this study, the first arrival peak from each cross-correlation signal was selected, and

273   the corresponding arrival times for the downstream (i.e., t_{S2} and t_{T2}) and upstream

274   transducers (i.e., t_{S1} and t_{T1}) are identified in Figs. 4c, 5c, 4d, and 5d, respectively, to

275   compute the velocity and water inflow. The discontinuities in the arrival time series data

276   indicate that these readings could not be selected because the recorded signal was

277 extremely weak. In other words, either the largest peak of each correlated signal did not

278 satisfy an acceptable signal-to-noise-ratio (SNR) threshold (10 dB), or it was

279 considerably scattered, and therefore, the arrival peak could not be defined accurately.

280 **Fig. 4** Arrival time records of 53-kHz system: sample of stack diagram of correlated
281 signals recorded on December 1, 2020, with a 5-min interval, (a) blue dots are the
282 selected peaks of the arrival times downstream and (b) red dots are the selected peaks of
283 the arrival times upstream. Time series plots of arrival times (in ms) obtained by (c) the
284 downstream (black) and (d) upstream (gray) transducers

285 **Fig. 5** Arrival time records of 30-kHz system: sample of stack diagram of correlated
286 signals recorded on December 1, 2020, with a 5-min interval, (a) blue dots represent
287 selected peaks of arrival times downstream, and (b) red dots represent selected peaks of
288 arrival times upstream. Time series plots of arrival times (in ms) obtained by (c)
289 downstream (black) and (d) upstream (gray) transducers

290

291 Remarkably, the recorded arrival times in Figs. 4c–d, and Figs. 5c–d ranged within the

292 expected values presented in Table 2. The arrival times fluctuated during the day and

293 night because of daily temperature variations. Once the arrival time records were defined,

294 the water velocity, flow direction, and inflow by FAT were calculated using Eqs. (2) and

295 (8).

296   3.2.2. Inflow velocity

297 The velocity resolution (u_r) of the FAT can be estimated using Eq. (9) (also see Fig. 6):

298
$$u_r = \frac{c_m^2}{4 \times R \times f} \qquad (9)$$

299   where f is the transducer frequency, R is the ray length (m), and $c_m = 1450$ m/s. Figure 6

300   demonstrates that the velocity resolution obtained by 53 kHz is 1.5 times greater than the

301   velocity obtained by the 30-kHz transducer (in the case of our transmission lengths). In

302   the present study, the velocity resolution acquired by $f = 53$ kHz (approximate ray length

303   along S1_S2 = 253.04 m) and $f = 30$ kHz (approximate ray length along T1_T2 = 287.5

304   m) is 0.039 m/s and 0.06 m/s, respectively.

305   **Fig. 6.** Velocity resolution of fluvial acoustic tomography (FAT) as a function of

306   acoustic ray length and transducer frequency; green and red dots denote velocity

307   resolution in accordance with distance and frequency for S1_S2 and T1_T2,

308   respectively

309   Kawanisi et al. (2012) revealed that the reliability of the FAT records increases as the

310   square root of the number of samples per ensemble increases. Hence, to decrease the

311   uncertainty of the FAT records, 60 samples in the case of 53 kHz (owing to the high

312   transmission rate, i.e., 10 s individually) and 30 samples in the case of 30 kHz were

313   averaged in this study. Consequently, the uncertainty caused by the low velocity

314   resolution could be reduced to $\frac{0.04}{\sqrt{60}}$=0.5 cm/s and $\frac{0.06}{\sqrt{30}}$ =1 cm/s for 53 kHz and 30 kHz,

315   respectively.

316   Figures 7a and 7b show the temporal variations in the cross-sectional mean velocities

317   along S1_S2 and T1_T2, respectively. The cross-sectional average velocity along S1_S2

318   was evidently very slow during the investigation period, with apparent positive and

319   negative fluctuations. Gaps in the velocity time series were generated because the original

320   arrival times were not recorded or were unreliable.

323   Similarly, the cross-sectional average velocity along T1_T2 was nearly constant, with

324   positive and negative fluctuations observed until the late morning of December 2, 2020.

325   However, the velocity became completely positive from the afternoon of the same day

326   along T1_T2 and S1_S2, which was expected because of the continuous water release

327   compared to the lower inflow rate. In fact, post December 4, 2020, the water level at the

328   dam lake had declined significantly near the left bank, particularly at T2, as illustrated in

329   the cross-sectional profile shown in Fig. 10b; therefore, the transducer and floating boat

330   remained almost dried on the bank, and consequently, reliable reciprocal sound

331   transmission along T1_T2 could not be accomplished afterwards. At midday on

332   December 2, 2020, the velocity was not determined because the battery voltages at T1

333   and S2 dropped and were replaced. The velocity data were processed using the mean filter

334   technique. This technique involves removing local variations caused by rough readings

335   and minimizing noise levels. To evaluate the mean filter of a dataset, every point is

336   replaced by the mean value in its range (r) neighborhood. Hence, in the case of the

337   velocity obtained by the 53 and 30-kHz datasets, 60 and 30 points were used during the

338   filtering process, respectively.

339   *3.3.Detection of flow direction and inflow estimation by fluvial acoustic tomography*

340   *(FAT)*

341   Owing to the difference in the velocity resolutions, only the computed flow direction and

342   inflow of optimal data records are shown. The water flow direction was computed

343   according to the main assumptions proposed in Section 3.2 and illustrated in Fig. 2.

344 Figure 8a presents the temporal variations in the ensemble-averaged inflow direction

345 between November 30, 2020 and December 1, 2020. In this figure, the flow direction

346 across S1_S2 is marked with four colors. These colors indicate the water direction over a

347 corresponding quadrant, according to the assumptions given in Section 2.2.2. Overall, the

348 absolute mean flow direction was 21.47°, and this value varied in different directions.

349 The findings in Fig. 8a reveal that the water direction mainly varied between Q1 and Q2.

350 **Fig. 8** Time series plots of a) water flow (inflow) direction according to its

351 corresponding quadrant, b) inflow estimated by fluvial acoustic tomography (FAT)

352 (black) and by HDMO (red), and outflow acquired by Haji Dam Monitoring Office

353 (HDMO; blue), and c) inflow by acquired by FAT using the mean flow direction $\theta =$

354 21.47° (black) and by HDMO (red), and outflow by HDMO (blue); Releasing period is

355 highlighted in blue

356 Figure 8b shows the temporal variations in the inflow acquired by FAT estimated from

357 Eq. (4) compared to those estimated by the HDMO. The inflow estimated by FAT and

358 that recorded by the HDMO on December 30, 2020 during release and very low release

359 conditions are moderately comparable with each other, with considerable variations in a

360 few periods. The large inconsistencies between FAT and HDMO estimates can be

361 attributed to the low resolution of velocity estimates by FAT (specifically for 30 kHz),

362 which decreased the accuracy of angle determination, or due to uncertainties in the stage-

363 storage term in the main water balance method for inflow calculation. Another possible

364 reason is the limitation of acoustic records in accurately determining the flow direction

365 under slow flow conditions, particularly during the transition of the water direction from

366 one quadrant to another.

367   Alternatively, considering the absolute mean value of the inflow direction as a fixed value

368   for inflow estimation using FAT (i.e., $\theta_1 = 21.47°$), the inflow rate estimated by FAT is

369   highly comparable to that reported by the HDMO, as depicted in Fig. 8c.

370   *3.4. Lake thermal stratification*

371   Thermal stratification is among the most important hydrological processes in lake

372   hydrodynamics. Figures 9a and 9b show the temperature along the water columns

373   measured at P1 to P4 (Fig. 1c) during fall and early winter, respectively. The seasonal

374   conditions are evidently influential. In other words, thermal stratification was observed

375   to be strong during the fall. The vertical temperature difference in the water surface within

376   a depth of 3 m was approximately 1.5 °C. However, the temperature dropped drastically

377   beyond 3 m ($\Delta T \approx 4.5$ °C) compared to the epilimnion temperature and averaged 18.25 °C.

378   However, during early winter, the vertical difference between the temperature of the

379   epilimnion and hypolimnion was approximately ($\Delta T \approx 2.5$ °C) and generally at an

380   average of 11.5 °C.

381   Given that the mean air temperatures near the lake area (recorded on the same days when

382   the lake temperature measurements were taken) were 18.86 °C and 9.9 °C, and the diurnal

383   fluctuations of air temperature can also be considered as another controlling factor.

384   The strong thermal stratification in the fall compared to that in winter can be attributed to

385   the strong solar radiation in the fall and the continuous exchange of heat flux on the water

386   surface, enabling continuous energy accumulation in the lake (Yang et al., 2018).

387   However, overcast weather coupled with strong winds that occur during winter creates

388   some stirring and partial homogenization of the water in the lake. Moreover, penetrative

389   convection occurs more easily at night, resulting in a decrease in the lake water

390   temperature and an additional degree of vertical mixing (Fig. 9b).

391   **Fig. 9** Temperature profiles along water columns measured at P1, P2, P3, and P4,

392   during (a) fall and (b) early winter

393   **4. Discussion**

394   *4.1.Hydrodynamics in light of hydroacoustics measurements*

395   The fundamental difference between a river and a lake is that the flow velocity of a lake

396   is far weaker and is not driven by gravity. In addition, the dynamic processes in a dam

397   lake are diverse and differ from those in rivers.

398   As demonstrated in this study, the travel-time principle is the backbone of the

399   tomographic measurements obtained using the FAT system. Reciprocal acoustic pulses

400   were triggered from both transducers concurrently, and the arrival times were determined

401   from the cross-correlation patterns. Accordingly, the velocity and discharge were

402   estimated using Eqs. (3) and (4), respectively.

403   The basic approach toward selecting the arrival times for upstream and downstream

404   stations is to select the greatest arrival peak for each correlation pattern (Chen et al. 2018).

405   However, Al Sawaf et al. (2020) found that found that implementing this approach is

406   imprecise. In this study, we observed certain periods of single arrival peaks and others of

407   double or multiple arrival peaks, where the largest arrival peak was observed in the

408   second group, as demonstrated in Figs. 4a, 4b, 5a, and 5b.

409   Two interesting concerns emerged from these results. The first concern is regarding the

410   certain periods showing only a single arrival peak, while other periods showing double

411   or multiple arrival peaks. The second concern is with respect to determining the arrival

412   peak to be selected for calculating the mean cross-sectional velocity when multiple arrival

413   peaks instead of a single peak, is encountered. With respect to the first concern, the sound

414   propagation of acoustic signals in shallow water environments is affected by several

415   factors, including bed material, bathymetry shape, presence of composite layer

416   stratifications of salinity, and different temperature layers (Nguyen et al., 2009; Thorne,

417   1998). The main hindrance for hydroacoustics experts is determining the exact path of

418   each triggered signal from a transmitter to receiver along the acoustic path because of the

419   above-mentioned features that control sound propagation in water. However, a simulation

420   for sound ray propagation along the transmission line can illustrate the behavior of a

421   transmitted acoustic ray in water. To accomplish this task, we used the method proposed

422   by Dushaw (1998) for acoustic ray simulation:

423
$$\frac{d\beta}{dr} = \frac{\partial c}{\partial r} \frac{1}{c} \tan \beta \ - \frac{\partial c}{\partial z} \frac{1}{c} \qquad (10a)$$

424
$$\frac{dz}{dr} = \tan \beta \qquad (10b)$$

425
$$\frac{dt}{dr} = \frac{1}{c} \operatorname{Sec} \beta \qquad (10c)$$

426   where β is the angle of the sound ray estimated from the horizontal and vertical axes, i.e.,

427   r and z, respectively; c is sound speed; and t is the time.

428 Ray simulations were performed for water temperature measurements collected during

429 early winter, as depicted in Fig. 9b. Figure 9b reveals that the temperature difference

430 between the epilimnion and hypolimnion can be estimated as 2.5 °C. In other words, the

431 sound speed at the bottom levels dropped by at least 10 m/s from the upper layers, as

432 shown in Fig. 10. The speed of sound in the water was computed using Eq. (11) proposed

433 by (Medwin 1975) as a function of water depth D (m) and temperature T (°C), whereas

434 in fresh water, the salinity (S) term was insignificant.

435 $$c = 1449.2 + 4.6T - 0.055T^2 + 2.9 \times 10^{-4}\, T^3 + (1.34 - 0.01T)\,(S - 35)$$

436 $$+ 0.016D \tag{11}$$

437 **Fig. 10** Ray simulated patterns along cross-sections of (a) S1_S2 and (b) T1_T2

438

439 Figure 10 and Table 3 present some interesting results. Along the transmission line S1_S2,

440 two arrival groups can be identified; the difference between the first arrival peak and the

441 second arrival peak was 0.27 ms, which is consistent with our observations. Likewise,

442 three arrival groups can be observed along T1_T2. The time difference between the first

443 arrival peak and the second arrival peak was 0.78 ms, which is also consistent with our

444 recorded signals.

445 **Table 3.** Results of ray simulation along S1_S2 and T1_T2

Transmission line: S1_S2			
Group number	Ray length (m)	Arrival time (ms)	Difference with the first arrival time (ms)

Group	I	253.82	173.74	0
(Black)				
Group	II	254.18	174.03	0.29
(Red)				
Transmission line: T1_T2				
Group	I	288.42	197.65	0
(Black)				
Group	II	289.80	198.43	0.78
(Red)				

446

447 The thermal stratification of the lake indicates that even in the case of relatively low

448 temperature differences between the epilimnion and hypolimnion during winter, as shown

449 in Fig. 9b, the cold temperature of the hypolimnion acts as a shield that obstructs and

450 weaken sound from reaching the warmer layers of the epilimnion for obtaining the largest

451 peak clearly as shown in Fig. 10. Figure 3b also shows that, remarkably, when water

452 release reached 15 m^3/s, the water temperature in the lake did not decrease rapidly. This

453 suggests that water release at this rate neither yields a notable feature nor causes apparent

454 thermal mixing.

455 To holistically elucidate the observed arrival groups along the two transmission lines with

456 respect to different water temperatures, the arrival times were estimated using the sound

457 speed values. The corresponding arrival times can be calculated by substituting the water

458 temperature readings obtained by the CTD (Fig. 9b) into Eq. (11). Hence, sound speeds

459 at –1 m and □3.8 m were 1456.35 m/s and 1448.90 m/s, respectively; the arrival times

460 are presented in Table 4. Notably, the calculated arrival times are comparable to the

461 simulated values listed in Table 3. Hence, the effect of different temperature layers on

462 generating multi-arrival peaks is elucidated.

463 **Table 4.** Arrival times estimated using Eq. (10) along two different temperature layers

Depth (m)	Temperature (°C)	Sound speed (m/s)	Arrival time (ms) = $\frac{Tranmission\ Length\ (m)}{Sound\ Speed\ (m/s)} * 1000$	
			S1_S2	T1_T2
–1.00	12.57	1456.42	173.7	197.40
–3.80	10.63	1449.11	174.6	198.4

464

465 The second concern emerges from these findings: which arrival peak should be selected

466 for the estimation of water velocity and discharge when multiple (instead of single) arrival

467 peaks are encountered (the first or delayed arrival peak)? Initially, various arrival time

468 groups were observed along S1_S2 and T1_T2. Nevertheless, in most cases, the received

469 signals from the cross-correlation patterns only showed one apparent single peak located

470 within the range of the first group, and some of the recorded signals showed double or

471 multiple peaks, where one peak appeared within the range of the first group (i.e., peaks

472 located along the red and blue peaks shown in Figs. 4a, 4b, 5a, and 5b), and the largest

473 peak arrived later. Therefore, we presumed the first peak to be desirable and not

474 necessarily the largest one. However, for a concrete demonstration, we estimated the

475 mean cross-sectional water temperature using the FAT system along T1_T2. In this

476 scenario, we used the arrival times of the first and delayed arrival peaks to estimate the

477 mean water temperature and then, compared the results to the temperature records

478 obtained by the water level-temperature logger, as shown in Fig. 11.

479   The different arrival time groups observed along T1_T2 in Fig. 11a were used to estimate

480   the sound speed using Eq. (12), and the mean water temperature along the transmission

481   line was determined by substituting the sound speed obtained by the FAT in Eq. (11).

482
$$c = \frac{R_i}{2} \times (\frac{1}{t_{T1}} + \frac{1}{t_{T2}}) \qquad (12)$$

483   where R_i is the ray length obtained from the ray simulation in Table 3 (i.e., $R_1 = 288.42$

484   m and $R_2 = 288.9$ m) because ray length is a function of water temperature and bathymetry

485   shape.

486   The trivial difference (i.e., 1 ms) between the first and delayed arrivals, as shown in Fig.

487   11a, resulted in a temperature difference estimated to be approximately 0.5 °C, which is

488   sizeable (see Fig. 11b); therefore, our assumption with respect to using the first arrival

489   peak appears to be valid.

490   **Fig. 11** a) Sample of arrival times with first and delayed arrival peaks and b) time-series

491   for mean water temperature estimated by FAT at 30 kHz (red) compared to mean water

492   obtained by water level-temperature logger (black)

493

494   *4.2. Internal waves*

495   One of the novel findings of this monitoring program was the ability to detect internal

496   seiches using a crossed acoustic path scheme (Fig. 8a). To illustrate this, Fig. 8a shows

497   the temporal variations in the flow direction; however, the flow mainly fluctuated

498   between the first and second quadrants (Q1 and Q2) over a period of approximately 3 h.

499   This phenomenon can be attributed to internal seiches in the lake and may have caused

500   the difference between the densities of the epilimnion and hypolimnion as a result of

501   inflow pulses into the lake. Mortimer (1952) stated that if exposing a stratified lake with

502   different densities at the epilimnion, ρ_e, and hypolimnion, ρ_h, to a steady wind, the

503   surface water moves toward the leeward bank due to frictional drag and wave action. The

504   wind generates a slope on the lake surface uphill in the same direction as the wind,

505   causing a return flow in the lower part of the epilimnion. Simultaneously, a sizable tilt

506   forms at the interface opposite to the surface tilt; this is accompanied by a thermocline

507   slope. In a two-layer stratified lake, the period (P) of the seiche can be estimated as

508   follows:

509
$$P = \frac{2 \times L}{\sqrt{g \times \{(\rho_h - \rho_e)/(\frac{\rho_h}{h_h} + \frac{\rho_e}{h_e})\}}} \qquad (13)$$

510   where L is the length of the water body; g is the acceleration of gravity; and h_e and h_h are

511   the average thicknesses of the epilimnion and hypolimnion layers, respectively. Upon

512   substituting the average density values of the epilimnion and hypolimnion obtained from

513   the CTD, the internal wave period was calculated to be 3 h, which confirms our

514   assumptions.

515   *4.3.Performance of inflow acquired by fluvial acoustic tomography (FAT) system*

516   To verify the performance of the inflow acquired by FAT (Q_{FAT}), four transects were

517   conducted as another independent technique along the direct line between the right and

518   left banks at points (R) and (L) using a Teledyne RDI Workhorse Monitor ADCP (Q_{ADCP})

519   operating at 1228.8 kHz, as shown in Fig. 1c. The data obtained via the Q_{ADCP} appear to

520   be comparable to those obtained via Q_{FAT} and Q_{HDMO}, as shown in Fig. 12a. The difference

521   among the three methods (Q_{FAT}, Q_{HDMO}, and Q_{ADCP}) is not very significant, considering

522   we worked with considerably slow velocities. Hence, the velocity, to the best of our

523   knowledge, was within the limit of most velocity-measuring instruments. The velocity

524   resolution of the acoustic doppler current profiler (ADCP) can be made reliable by

525   averaging a large set of ping data. Unfortunately, we were unable to use a bottom-fixed

526   ADCP because the dam lake was utilized by certain local fishermen. In addition,

527   deploying a fixed ADCP above the accumulated sediments in the center of the lake was

528   unsafe.

529   In the absence of a reliable inflow monitoring method, we cannot accurately verify the

530   ultimate performance of the FAT system. Figure 12b reveals a type of low resolution

531   associated with dam inflow records obtained by the HDMO, compared with the measured

532   stage. Therefore, the monotonous inflow behavior can be understood by observations

533   made using the HDMO.

534   **Fig. 12** a) Comparison between inflow acquired by fluvial acoustic tomography (FAT;
535   black), Haji Dam Monitoring Office (HDMO; red), acoustic doppler current profiler
536   (ADCP; green), and outflow by HDMO (blue), and b) association between stage and
537   inflow as recorded by HDMO

538

539   *4.4.Comparison with previous studies and scope for future research*

540   Most of the previous monitoring applications via the FAT system were accomplished

541   using a 30 kHz transmission frequency. However, the 30-kHz system has a certain range

542   of transmission length between a pair of transducers, and the minimum water depth must

543   exceed ~0.5 m for effective use (Razaz et al. 2015). Consequently, in 2016, the first

544   version of the FAT system that can be operated using 53 kHz frequency was developed

545   for use in relatively shallower and narrower streams, with higher velocity resolution.

546   Bahreinimotlagh et al. (2016) performed the first discharge monitoring via a cross-

547   transmission configuration using one pair of 30-kHz systems and another of 53-kHz

548   systems in a mountainous river. Their findings confirmed that the velocity resolution was

549   augmented twice when using 53 kHz, with a minimum recorded value of 0.2 m/s.

550   Recently, (Al Sawaf et al. 2020) successfully acquired accurate river velocity for very

551   shallow conditions using a 53-kHz system. The minimum acquired velocity was 0.1 m/s

552   (obtained for a cross-section), with a minimum depth of 28 cm.

553   In the current observation, two different frequencies were used in a very slow flow

554   condition. Figures 6 and 7 demonstrate that the current velocities captured at 53 kHz seem

555   to be more precise than those obtained at 30 kHz, with a mean absolute cross-sectional

556   velocity of 1.5 cm/s, which is a significant accomplishment.

557   The precision of the hydroacoustic measurements depends substantially on determining

558   the exact arrival time, and even a mistake as tiny as a sub-millisecond can generate

559   enormous errors. Hence, the FAT system can provide reliable measurements even in

560   extremely slow water-velocity environments. As seen in Fig. 11, the delayed arrival times

561   resulted in increased temperatures compared to the first arrival times.

562   Another interesting feature in this study is that we improved the flow direction approach

563   proposed by Bahreinimotlagh et al. (2016) for use in different situations. Our improved

564   approach is flexible and appropriate for determining the flow direction not only in cases

565   of dam inflow but also in various circumstances, such as tidal rivers (wherein the flow

566   shifts from landward to seaward and vice versa), and can clarify the occurrence of

567   negative inflow periods. However, we used the temporal variations of the ensemble

568   inflow direction because we assumed that the reservoir inflow direction would not vary

569   significantly over a short period.

570   Although some of our findings are preliminary, our results are encouraging. The FAT

571   system is capable of capturing flow direction and water velocity; therefore, future studies

572   should consider longer periods to determine the linkage between a fluctuating inflow,

573   while maximizing power generation capacity.

574   Moreover, future studies should examine the hysteresis relationship of the variation in the

575   water flow direction during the opening and closing of the dam gate. Additionally, the

576   relationship between flow direction and inflow velocity can be used to propose another

577   superior equation to supplement the traditional water balance equation because this

578   information captures the velocity along the flow direction in the entire cross-section

579   rather than in a small portion (H-ADCP).

580   Finally, future research should utilize the findings of this study to improve existing

581   analytical models and seek the most accurate inflow quantities using the travel-time

582   principle of underwater acoustics.

583   **5. Conclusions**

584   The ability to acquire reliable real-time and continuous records of flow data can facilitate

585   optimal utilization of water resources, elucidate hydrologic information, and allow for

586   optimal ecological and societal outcomes. In this study, we observed the water inflow to

587   a dam lake using the FAT system, based on the travel-time approach. The main goal of

588   this study is to offer a practical and reliable monitoring approach for understanding the

589   inflow to a lake, investigating the behavior of underwater acoustic communications

590   within very slow flow environments, and analyzing the related hydrological processes.

591   Two pairs of FAT systems were placed diagonally upstream of a dam lake at two different

592   frequencies. We upgraded the flow direction estimation based on travel-time behavior.

593   Additionally, we discussed the importance of using accurate tomographic data in inflow

594   monitoring and demonstrated that a small mistake in tomographic records (even by a sub-

595   millisecond) could generate substantial errors.

596   Generally, inflow monitoring based on the travel-time approach appears to be practical

597   and can be considered as a promising and competitive application. In this study, the flow

598   direction was continuously deduced via reciprocal sound transmission using a cross-

599   configuration transmission, and the flow direction equation was improved for

600   applicability to a fluctuating water flow environment. However, the precision of the

601   values is a function of velocity resolution. Our findings reveal that the smallest mistake

602   in selecting the exact arrival times (even by a sub-millisecond) can generate a substantial

603   error. Hence, the FAT system can yield reliable measurements. An interesting study

604   finding is the ability of the FAT system to detect the presence of internal waves (i.e.,

605   seiches) based on the travel-time approach and upgraded flow direction equation.

Figures

Figure 1

a) Location of the observation site; b) map showing Gōno River, Haji Dam, and Yachiyo Lake; and c) study area map with inflow measurement zone and instrument positions Note: The designations employed and the presentation of the material on this map do not imply the expression of any opinion

whatsoever on the part of Research Square concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries. This map has been provided by the authors.
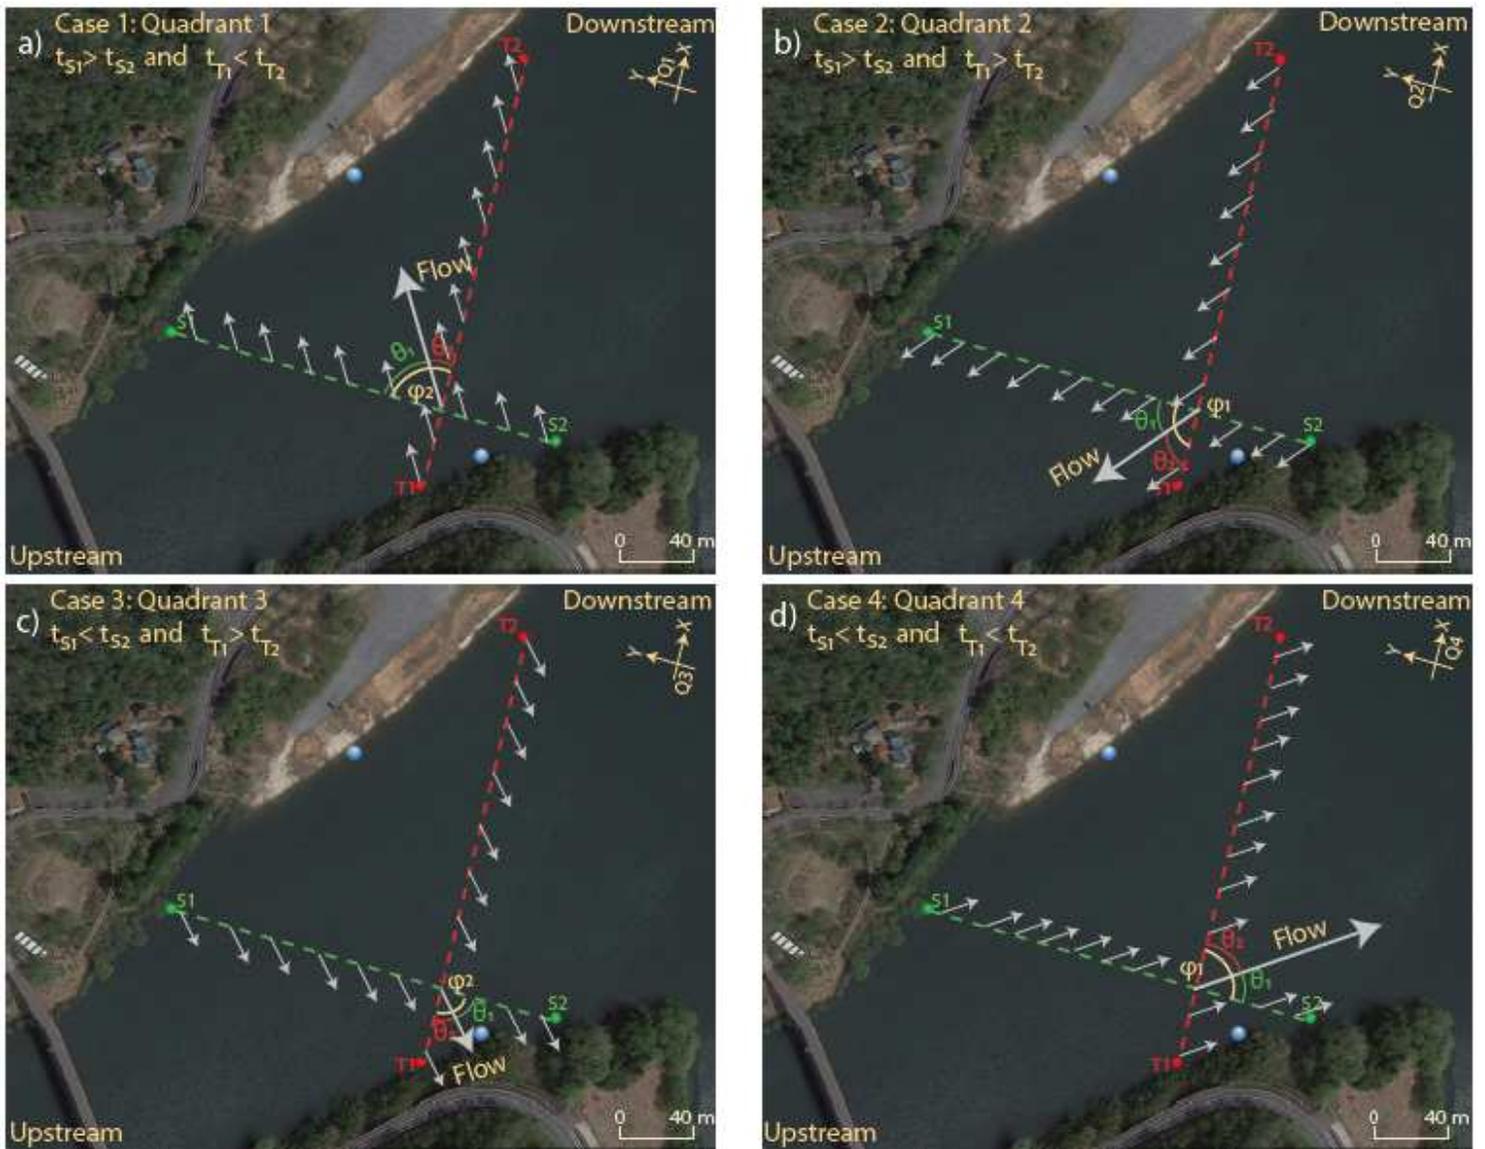

Figure 2

Visualization of flow direction over proposed axes according to recorded arrival times
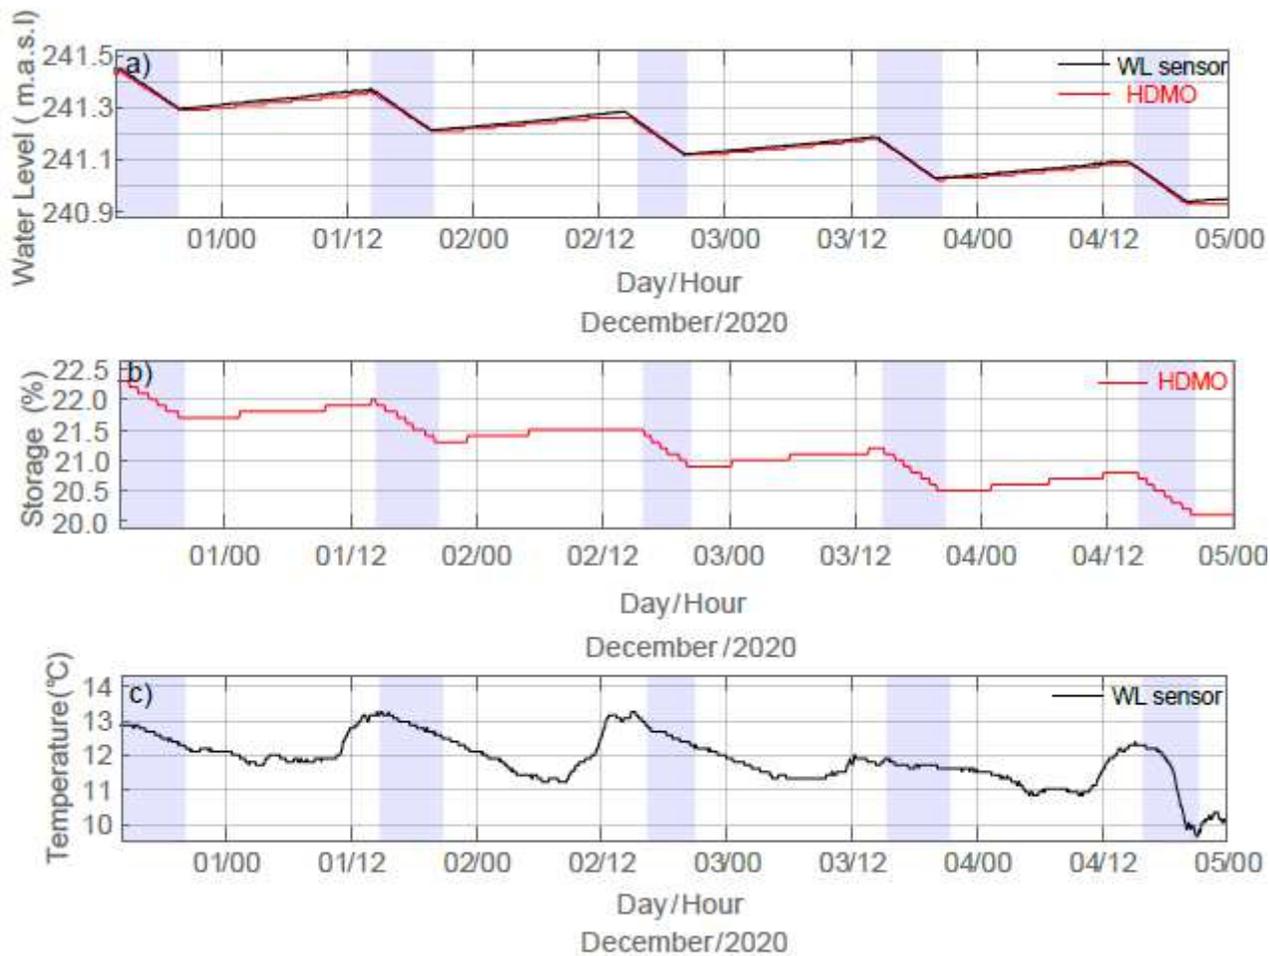

Figure 3

Time series plots of a) mean water level recorded by Haji Dam Monitoring Office (HDMO; red) and water level-temperature sensor (black), b) temporal variation of storage, and c) average water temperature. Releasing periods are shaded in blue
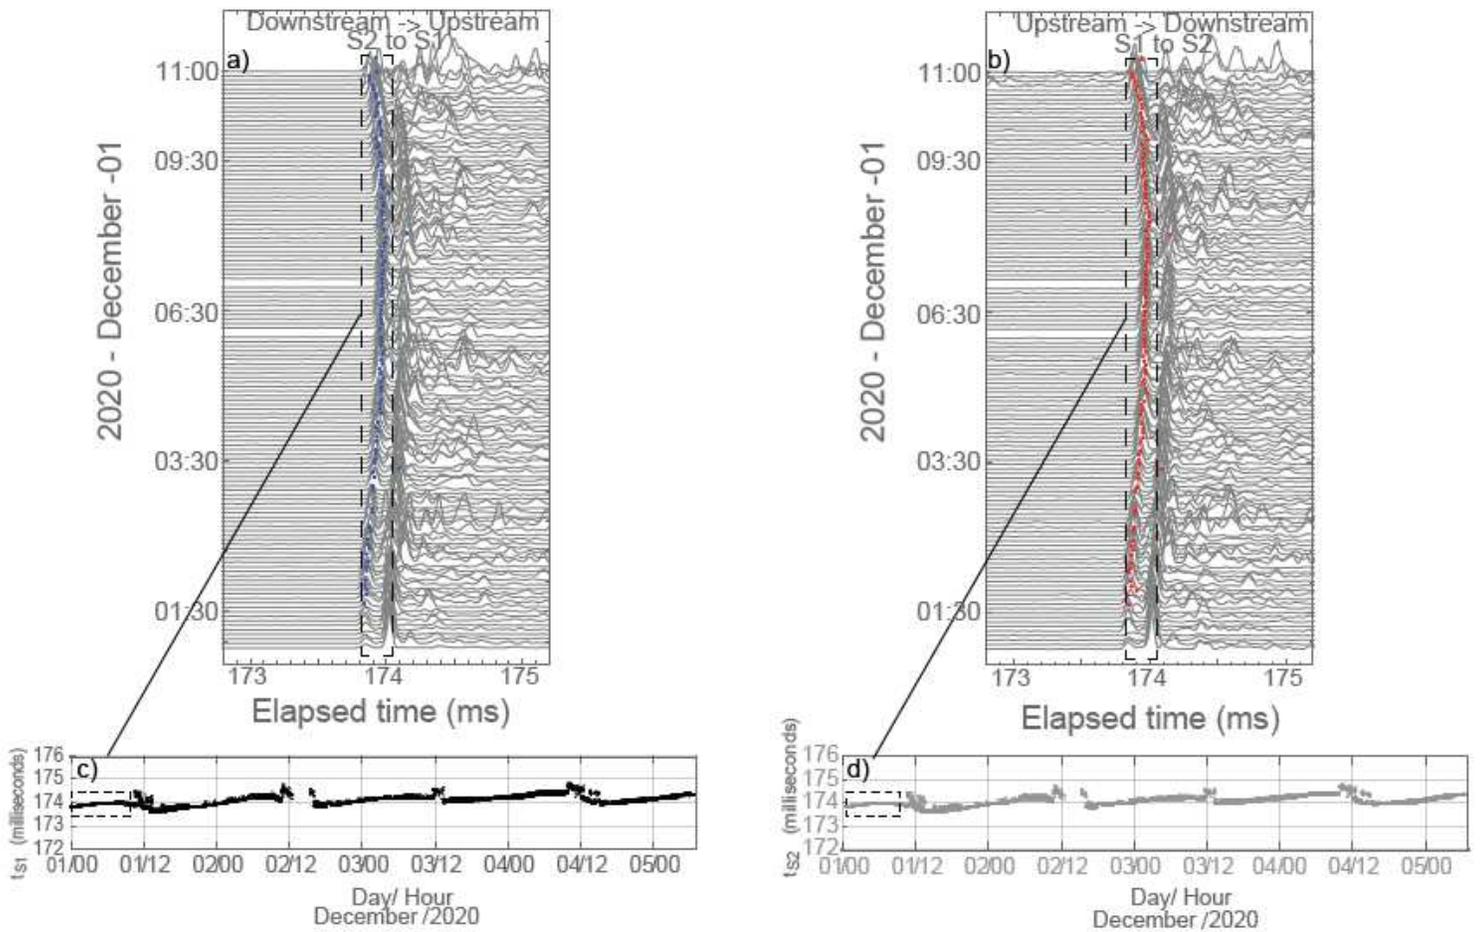

Figure 4

Arrival time records of 53-kHz system: sample of stack diagram of correlated signals recorded on December 1, 2020, with a 5-min interval, (a) blue dots are the selected peaks of the arrival times downstream and (b) red dots are the selected peaks of the arrival times upstream. Time series plots of arrival times (in ms) obtained by (c) the downstream (black) and (d) upstream (gray) transducers
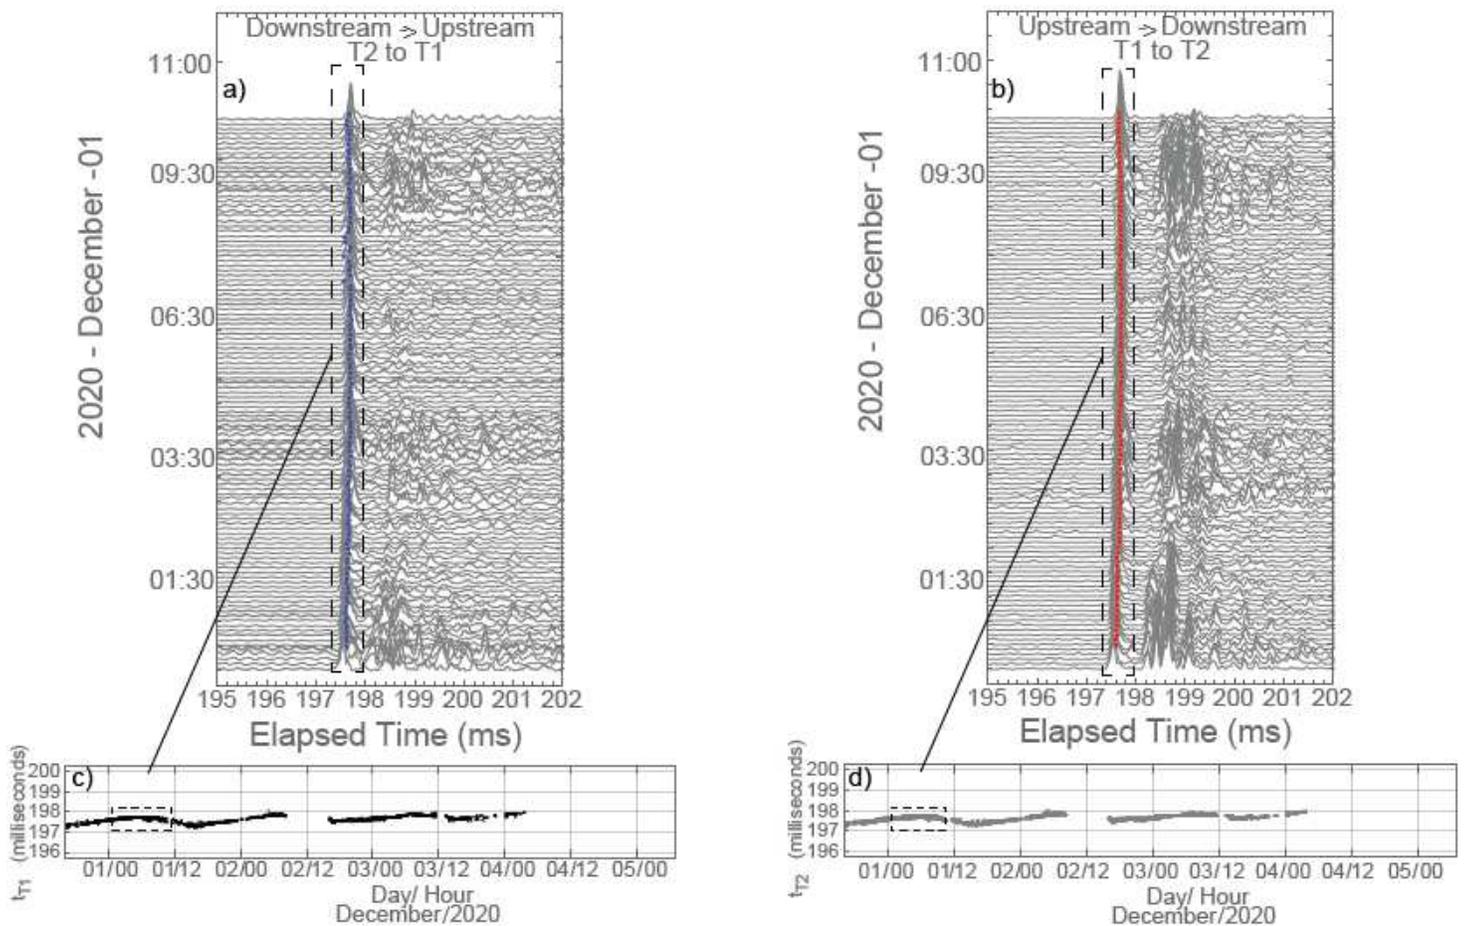

Figure 5

Arrival time records of 30-kHz system: sample of stack diagram of correlated signals recorded on December 1, 2020, with a 5-min interval, (a) blue dots represent selected peaks of arrival times downstream, and (b) red dots represent selected peaks of arrival times upstream. Time series plots of arrival times (in ms) obtained by (c) downstream (black) and (d) upstream (gray) transducers
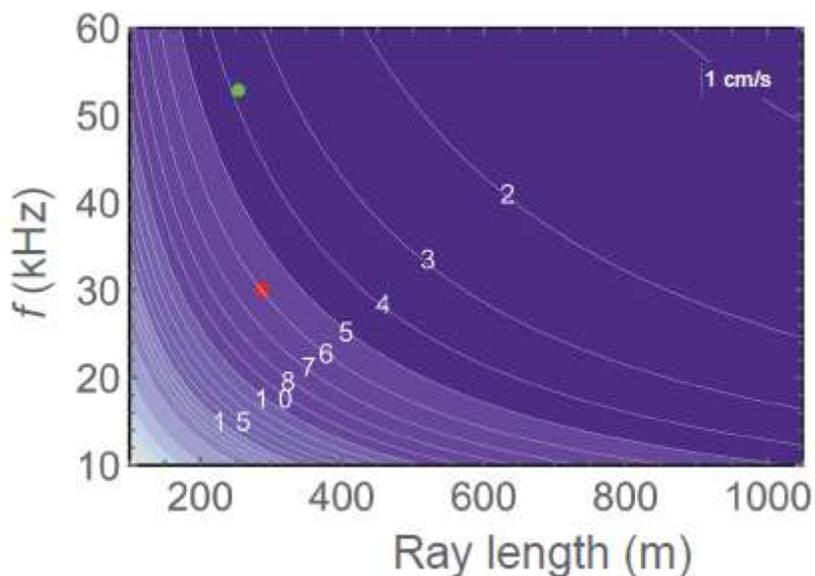

Figure 6

Velocity resolution of fluvial acoustic tomography (FAT) as a function of acoustic ray length and transducer frequency; green and red dots denote velocity resolution in accordance with distance and frequency for S1_S2 and T1_T2, respectively
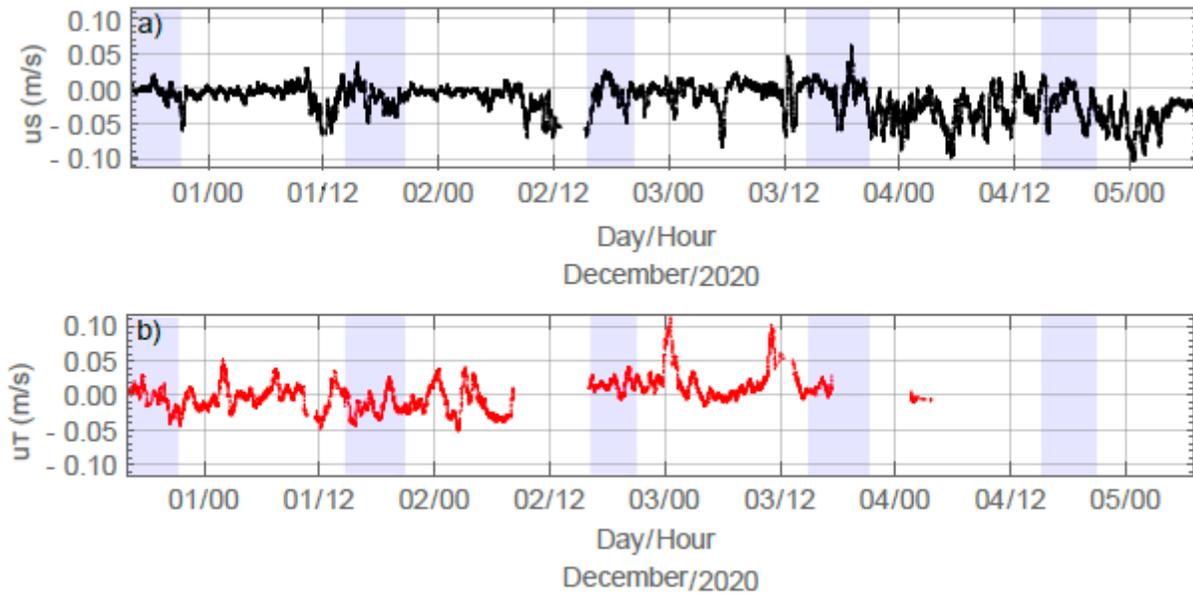

Figure 7

Mean average velocity along transmission lines: (a) S1_S2 (black), and (b) T1_T2 (red). Releasing periods are highlighted in blue
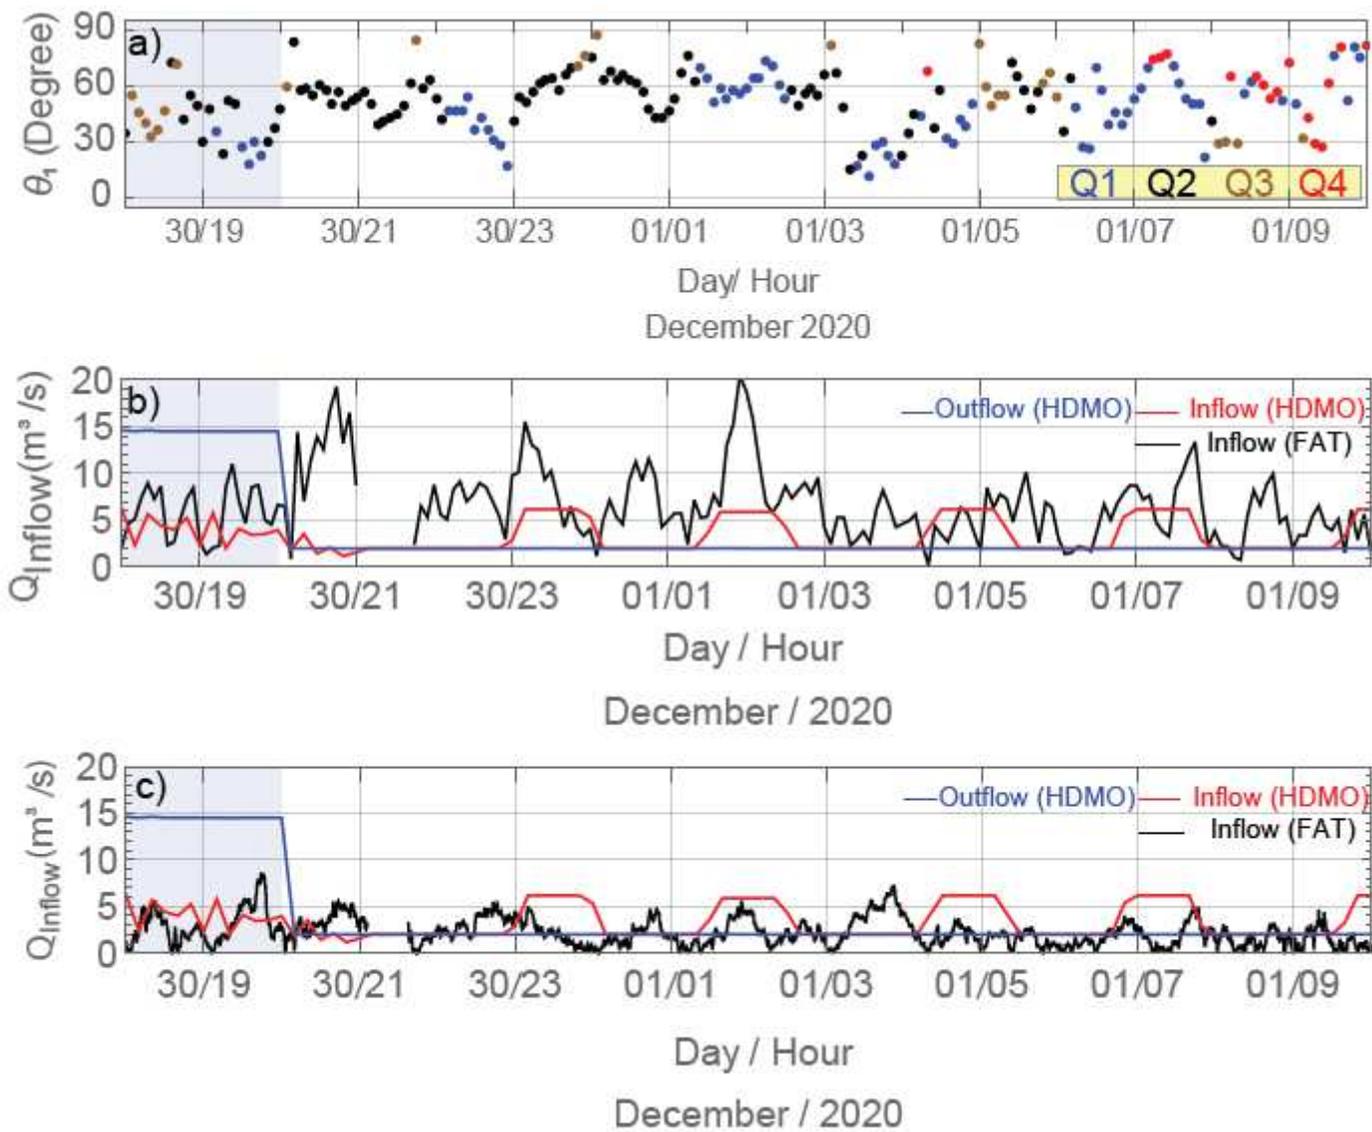

Figure 8

Time series plots of a) water flow (inflow) direction according to its corresponding quadrant, b) inflow estimated by fluvial acoustic tomography (FAT) (black) and by HDMO (red), and outflow acquired by Haji Dam Monitoring Office (HDMO; blue), and c) inflow by acquired by FAT using the mean flow direction θ = 21.47° (black) and by HDMO (red), and outflow by HDMO (blue); Releasing period is highlighted in blue
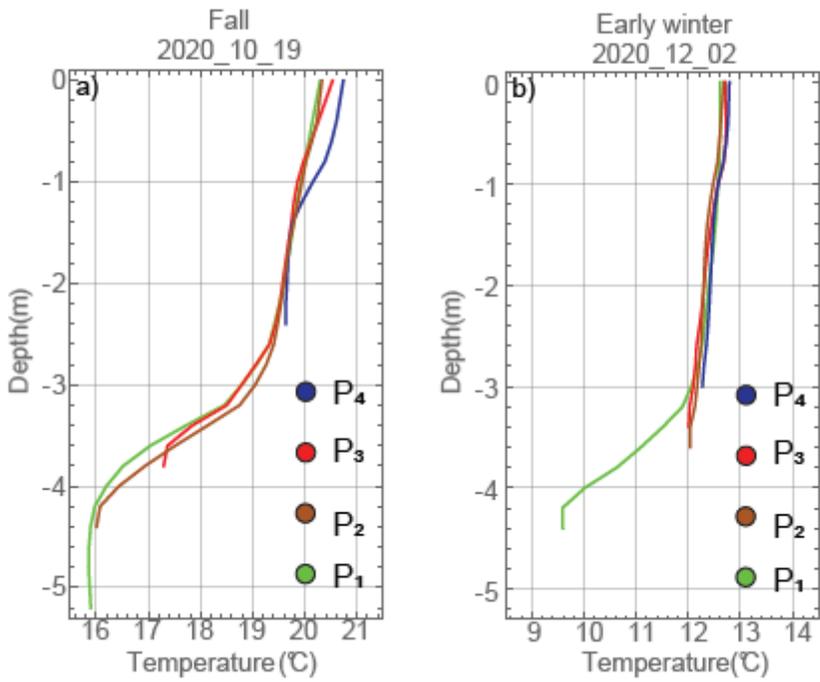

Figure 9

Temperature profiles along water columns measured at P1, P2, P3, and P4, during (a) fall and (b) early winter
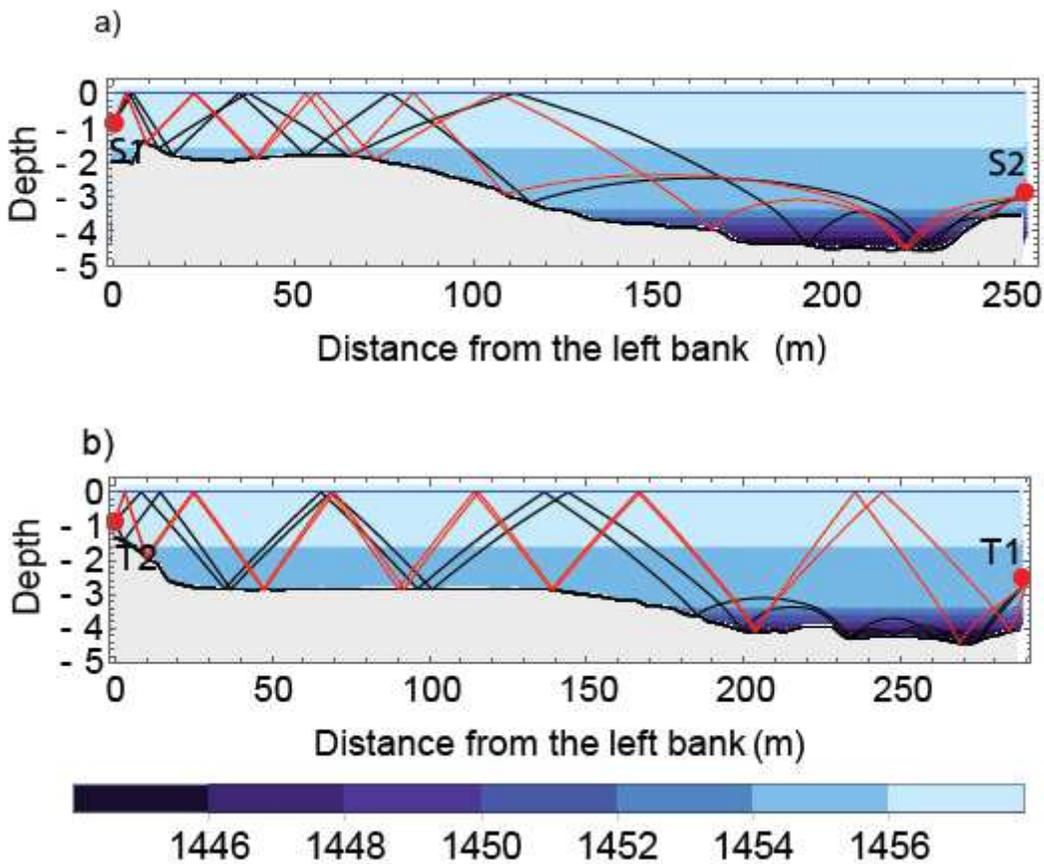

Figure 10

Ray simulated patterns along cross-sections of (a) S1_S2 and (b) T1_T2
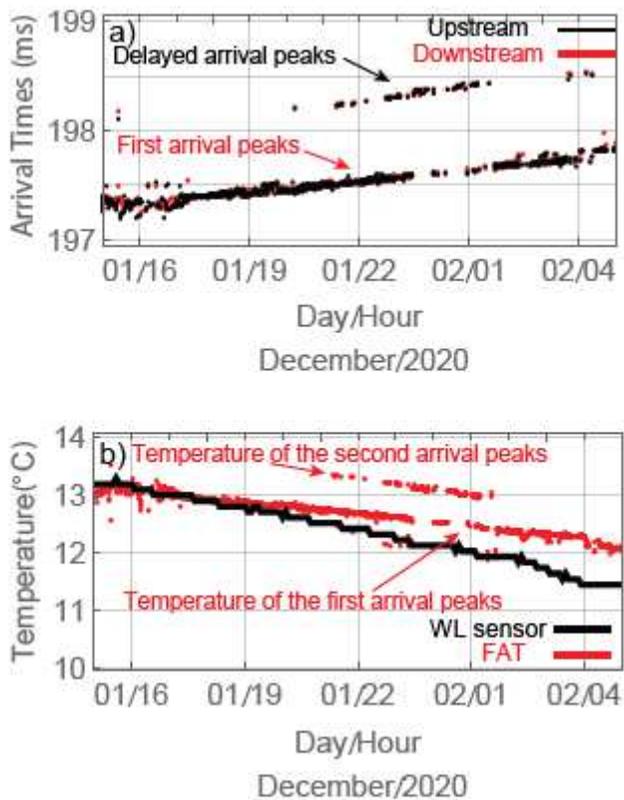

Figure 11

a) Sample of arrival times with first and delayed arrival peaks and b) time-series for mean water temperature estimated by FAT at 30 kHz (red) compared to mean water obtained by water level-temperature logger (black)
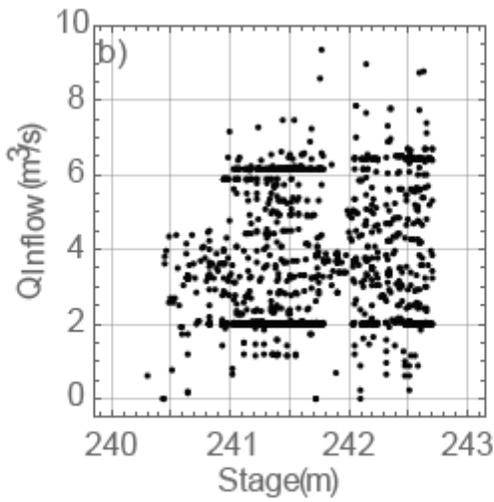

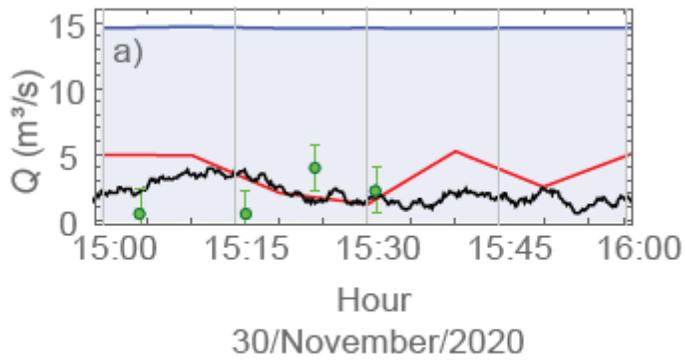

Figure 12

a) Comparison between inflow acquired by fluvial acoustic tomography (FAT; black), Haji Dam Monitoring Office (HDMO; red), acoustic doppler current profiler (ADCP; green), and outflow by HDMO (blue), and b) association between stage and inflow as recorded by HDMO
