22
23 **Abstract**

24 Ambrosia beetles of the *Euwallacea fornicatus* species complex are emerging tree pests with a broad host range
25 including important agricultural crops. Native to Southeast Asia, these species were introduced into various countries,
26 where they cause considerable damage to many tree species. Here we report several outbreaks of *E. fornicatus* s.l. in
27 Europe. The first individuals were found in 2017 in a palm house of a botanical garden in Poznan (Poland) whereas in
28 2020 an outbreak was detected in a tropical greenhouse in Merano (Italy). In 2021, two additional outbreaks were
29 detected in two greenhouses in Germany, in Erfurt and Berlin. For the latter cases it was possible to trace back the
30 invasion to a distributor of exotic plants in the Netherlands where several infected plants were detected. Molecular
31 analysis show that individuals from Poland and Italy are genetically identical but belong to a different mitochondrial
32 clade than individuals in Germany which are identical to most individuals of two greenhouses in the Netherlands.
33 Moreover, in the two greenhouses in the Netherlands we found beetles that belong to another haplotype of *E. fornicatus*
34 and two haplotypes of *E. perbrevis*, a species in the *E. fornicatus* complex, which has not been previously intercepted in
35 Europe. Our study provides novel insights into the invasion history of *E. fornicatus* and the first eradication measures in
36 Europe. Considering the high potential of introduction and establishment of *Euwallacea* ambrosia beetles, particular
37 attention should be paid to monitor the presence of these pests in greenhouses across Europe.

58

59 **Introduction**

60 Members of the *Euwallacea fornicatus* species complex (Coleoptera: Curculionidae: Scolytinae) are severe agricultural
61 pests in most parts of the world (Beaver 1976; Li et al. 2016; Ge et al. 2017). They are one of a few examples of
62 ambrosia beetles that are able to infest healthy plants (Gomez et al. 2019). The *E. fornicatus* species complex has a
63 broad host range of 412 plant species in 75 families (Gomez et al. 2019) including important agricultural crops such as
64 tea (*Camellia sinensis*), mango (*Mangifera indica*) and avocado (*Persea americana*) (Eskalen et al. 2013; Carrillo et al.
65 2016); Danthanarayana 1968; Yamaguchi et al. 2006). They are associated with at least three symbiotic fungi *Fusarium*
66 *euwallaceae*, *Graphium euwallaceae* and *Paracremonium pembeum* (syn. *Acremonium pembeum*) (Carrillo et al. 2016;
67 Freeman et al. 2016; Lynch et al. 2016). Some of these vectored fungi are plant pathogens causing avocado dieback in
68 California (USA) and Israel (Eskalen et al. 2012, 2013; Freeman et al. 2013).

69

70 *Euwallacea fornicatus s.l.* is native to Southeast Asia with confirmed records in China, Japan, Malaysia, the
71 Philippines, Taiwan, Sri Lanka, Thailand, and Vietnam (CABI 2021, Stouthamer et al. 2017). Outside its native range,
72 *E. fornicatus s.l.* invaded various countries in North and Central America (USA, Panama, Costa Rica), Africa (South
73 Africa, Réunion), Oceania (Australia, Papua New Guinea, Fiji and other countries), and Israel (Kirkendall and
74 Ødegaard 2007; Cooperband et al. 2016, CABI 2021). In Europe, *E. fornicatus s.l.* is considered a quarantine pest and is
75 included in the Annex II Part A within the group “Scolytidae spp. (non-European)” (Commission Implementing
76 Regulation EU 2019/2072). Its explicit listing in Annex II is anticipated by the end of 2021. Its wide host range makes
77 *E. fornicatus s.l.* a serious threat for agriculture but also forestry, ornamental plants, and botanical gardens.

78

79 Several outbreaks were recently discovered in tropical greenhouses of botanical gardens in Europe. In 2017, specimens
80 of *E. fornicatus* were found on a sacred fig (*Ficus religiosa*) tree in a palm house in Poznań, Poland (EPPO 2019),
81 whereas various tropical plants have been attacked by *E. fornicatus* in a greenhouse in Merano, Italy (EPPO 2020).
82 Recently, two other cases have been reported in Germany in two tropical greenhouses in Thuringia (EPPO 2021a) and

83 Berlin (EPPO 2021b) and in a greenhouse in the Netherlands (EPPO 2021c). Although tracing information of
84 consignments has been used to establish the origin of infested plants, analysis of molecular data may provide direct
85 insights into the invasion history of *Euwallacea* and thus into the dynamics of introduction events across the different
86 locations. Here we perform a comparative genetic analysis of insects from different locations in Europe and attempt to
87 trace back the introduction pathway of the beetles. Moreover, we report the subsequent eradication measures. Our study
88 provides new insights into the introduction and the subsequent steps to eradicate these invasive insect pest species.

89

90 **Materials and methods**

91 *Detection and identification*

92 A sacred fig tree (*Ficus religiosa*) in the Poznań Palm House (Poland) showed branch dieback and visible frass, typical
93 symptoms for infestation with ambrosia beetles in March 2017. An approximately 1 m long branch of the tree was cut
94 and placed in a breeding container. Emerging beetles were collected for taxonomic identification. In April 2020, several
95 trees in the tropical greenhouse of the Gardens of Trauttmansdorff Castle in Merano (Italy), showed boreholes and
96 ejection of wooden debris. Emerging insects were directly collected from infested plants, from the walls of the
97 greenhouse and dissected from trap logs deployed in the greenhouse. In addition, two plants, one *Mangifera indica* and
98 one *Tectona grandis*, showed symptoms of a bark beetle infection in a tropical greenhouse in Erfurt (Germany) in
99 January 2021 and two months later several plants in a greenhouse in Berlin (Germany) showed resin flows on stems and
100 boreholes with small protruding tubes of compacted sawdust. Emerging beetles were collected and stored in ethanol. In
101 the Netherlands, several plants were found to be infested at two plant nurseries (NL1 and NL2) and where beetles were
102 extracted.

103

104 Identification of the insect material was carried out using taxonomic keys available in the literature (Smith et al. 2020;
105 Wood and Bright 1992; Rabaglia et al. 2006; Wood 2007; Smith et al. 2019) by the Poznań University of Life Sciences
106 in Poland, by the Laboratory for Virology and Diagnostics of the Research Centre Laimburg in Italy and by the federal
107 plant protection agencies in Thuringia and Berlin and the National reference laboratory of the Julius-Kühn Institute
108 (JKI) in Braunschweig in Germany and by the National Reference Centre of the NPPO in the Netherlands.

109

110 *DNA extraction and sequencing*

111 A total of 32 individuals were analyzed including three individuals from Poland, 9 individuals from Italy, three
112 individuals from Erfurt and 17 from Berlin. Individuals were genotyped using the primers Lep-R1 (Hebert et al. 2004).
113 Moreover, in the Netherlands, in a total of 32 beetle specimens from the Dutch outbreak locations (18 beetle specimens
114 from NL1 and 14 beetle specimens from NL2) were included in the analysis. Details about the extraction protocol, PCR
115 conditions and sequencing can be found in supplementary document S1.

116

117 *Cluster analysis*

118 Relationship of the obtained sequences was determined using 83 partial mitochondrial COI sequences obtained from
119 NCBI GenBank and the 64 partial COI sequences generated in this study. Sequences were aligned using the MAFFT
120 aligner (Katoh et al. 2002; Katoh and Standley 2013) incorporated in Geneious Prime v2021.1.1 (BioMatters, New
121 Zealand). Terminal positions in the alignment that were not covered by all sequences in the dataset were masked
122 resulting in a 564 bp alignment used for clustering analysis. A maximum likelihood tree was constructed with FastTree
123 (Price et al. 2010) using the generalized time-reversible (GTR) model and 1,000 bootstraps to determine confidence

124 levels of internal nodes. The *cox1* sequence of *Euwallacea andamanensis* isolate PR13-238 (KU727039) was used to
125 root the *E. fornicatus s.l.* sequences.

126

127 *Eradication and surveillance*

128 In Poland, immediately after the outbreak was noticed, actions limiting its spread were undertaken. The whole sacred
129 fig tree was covered with Storanet® BASF Agrar (insect-proof net impregnated with alpha-cypermethrin) and the tree
130 was subsequently removed and burnt under controlled conditions. The soil around the roots was excavated and the
131 surrounding area was treated with the fungicide Topsin M (Thiophanate-Methyl, 100 ppm concentration). Beetle
132 surveillance with 4 triangle barrier traps IBL-2 (baited with 98% ethanol) started immediately and continued for a year
133 after removal of the infested tree. Furthermore, plant health conditions in the palm house were monitored by visual
134 observation of symptoms.

135

136 After the first detection of *E. fornicatus* in Italy, an intense monitoring has started inside the greenhouse and in the
137 surrounding area. Due to the advanced outbreak, all the plants in the greenhouse, including their roots, were removed
138 and destroyed under official control in June 2021. The greenhouse was also subjected to solarization for a period of
139 three months. Simultaneously, three sticky traps baited with quercivorol and alpha-copaene according to (Kendra et al.
140 2019) and several trap logs of *Acer negundo* (diameter 4-10 cm, length 30-60 cm) were placed inside the greenhouse to
141 verify the possible presence of adults. In the area external to the greenhouse, two traps were deployed at 500 and 1000
142 m from the tropical greenhouse in each cardinal direction, for a total of eight traps. All traps were weekly checked.
143 Visual inspections from the ground, ladders and hoisting platforms were implemented in- and outside of the infested
144 greenhouse. Known host plants of the beetle (*Acer* spp., *Citrus* spp., *Platanus* spp., etc.) were monitored for boreholes
145 especially after favorable weather conditions. Additionally, weakening tree parts or branches were inspected for
146 symptoms.

147

148 After the introduction in Germany, monitoring inside and outside the respective greenhouse have been initiated, using
149 the setup described above, consisting of trap logs containing quercivorol pheromones. In the plant nurseries of
150 Netherlands, ethanol and acetic acid-baited traps were placed in all greenhouse compartments for one week (18 traps at
151 NL1, 6 traps at NL2). Later sticky traps baited with quercivorol and alpha-copaene were placed in the greenhouse
152 compartments at eight positions in both greenhouses.

153

154 **Results**

155 *Detection and eradication*

156 In Poland, the sacred fig sample yielded over 1,000 specimens of *E. fornicatus*. No beetles were caught by the traps for
157 one year after the first detection. Plants, occurring in the same pavilion as the infested sacred fig and plants in
158 neighboring pavilions, which were subjected to regular inspections did not show symptoms of ambrosia beetles and
159 fungal infection.

160

161 In Italy, a total of 28 trees of 21 different species (*Annona muricata*, *Artocarpus heterophyllus*, *Averrhoa carambola*,
162 *Bixa orellana*, *Bulnesia arborea*, *Cananga odorata*, *Clausena lansium*, *Crescentia cujete*, *Debregeasia edulis*,
163 *Dimocarpus longan*, *Ficus altissima*, *Ficus* sp., *Justicia* sp., *Kigelia africana*, *Melicoccus bijugatus*, *Mangolia*
164 *champaca*, *Millettia brandisiana*, *Persea americana*, *Terminalia catappa*, *Terminalia buceras*, *Theobroma cacao*)

165 showed boreholes and ejection of wooden debris. Intensity of infestation, diameter of infested trees and distribution of
166 the boreholes on the plant differ strongly between species and individual plants. *Annona muricata* and *Bixa orellana*
167 were the most heavily infested plants, showing more than five holes per dm². The highest density of boreholes was
168 observed next to fresh and older cut branches and on thinner parts in the crown/upper stem. The presence of boreholes
169 was also observed in twigs less than 2 cm of diameter of *Dimocarpus longan* and *Justicia spp.* trees. No beetles were
170 caught in the traps deployed outside of the tropical greenhouse and visual inspection of susceptible host trees did not
171 result in finding of symptoms of beetle attack.

172

173 The two recent findings in Germany revealed that in Erfurt just two plants, one *Mangifera indica* and one *Tectona*
174 *grandis*, were attacked by *E. fornicatus*, whereas in Berlin 136 shrubs and trees of *Clusia rosea*, *Heteropanax sp.*, *Ficus*
175 *sp.*, and *Mangifera indica* showed symptoms. All infested plants were destroyed and surveillance started in both
176 localities.

177

178 In the Netherlands, at both locations all infested plants were destroyed. The sale and transport of all woody plants and
179 palms (Arecaceae) in the two greenhouses in the Netherlands was put on hold followed by intensive visual inspection of
180 all consignments by the phytosanitary authorities.

181

182 *Reconstruction of the invasion*

183 Trace-back investigations revealed that the *F. religiosa* tree infected with *E. fornicatus* in Poland was imported in
184 November 2016 from the Netherlands. The infection has already been detected five months later and subsequent
185 phytosanitary measures impeded the dispersion to other trees. The advanced outbreak in Italy with 21 different species
186 attacked at the time of detection, hindered a detailed reconstruction of the invasion. The greenhouse in Italy was
187 established in 2014 and most plants were purchased between 2013 and 2014. No symptoms of beetle attack were
188 reported in the first years following the establishment. Additionally, one *T. cacao* plant was replaced in 2018, which
189 was the same that two years later was discovered to be attacked by *E. fornicatus*. Both infested plants in Erfurt, and
190 most of the infested plants in Berlin were acquired and imported from a distributor of exotic plants in the Netherlands in
191 2020.

192

193 Following a trace-back of the notification in the Erfurt case, we were able to link these infestations to a Dutch
194 greenhouse for commercial sale of tropical plants (NL1). A follow up survey resulted in several trees that were attacked
195 by ambrosia beetles. Samples were collected from a *Ficus microcarpa* individual that contained specimens of the
196 *Euwallacea fornicatus s.l.* in March 2021. Additionally, beetles were collected from *Bauhinia x blakeana*, *Ficus*
197 *microcarpa* 'Panda', *Ficus sp.*, *Ficus maclellandii* 'Alii' and *Ficus* 'Amstel King' whereas one individual was collected
198 from a trap. A following survey in another greenhouse associated with the company (NL2) resulted in the discovery of
199 several additional symptomatic trees. At location NL2, individuals were collected from *F. benjamina* 'Exotica', *F.*
200 *foliolo* and *Ficus lyrata*. A total of 32 individuals from the two populations in the Netherlands (18 from NL1, 14 from
201 NL2) were subsequently genotyped and included in our cluster analysis.

202

203 *Molecular identification*

204 All individuals from Poland and Italy were genetically identical (Genbank acc. Number TBA) but different from the
205 individuals found in Germany and the Netherlands. The haplotype described in Poland and Italy clustered with a

206 haplotype of the PSHB clade which according to Smith et al. (2019) is *E. fornicatus*. However, none of the haplotypes
207 described in *E. fornicatus* populations in their native and invasive range were identical to the haplotype described in
208 these two localities. The cluster analysis showed that the prevalent COI haplotype in Europe was most related to a
209 haplotype present in Vietnam (Stouthamer et al. 2017; Fig. 1). In contrast all individuals from Germany and the
210 Netherlands share the same haplotype (Genbank acc. Number TBA) which is related to a population previously
211 genotyped in Taiwan (Stouthamer et al. 2017). Moreover, two individuals from the Netherlands (NL2) belonged to a
212 PSHB haplotype that did not match any of the haplotypes uncovered at the other locations.(Stouthamer et al. 2017)
213
214 Sequence analysis of 32 individuals from the Netherlands revealed four haplotypes. Thirteen individuals of location
215 NL1 clustered with *E. fornicatus* in the PSHB clade 3A (Stouthamer et al. 2017) whereas five individuals belonged to
216 two haplotypes of the TSHBa clade (Genbank acc. Number TBA) which according to Smith et al. (2019) is now
217 considered *Euwallacea perbrevis*. All sequenced individuals from NL2 belonged to two mitochondrial haplotypes that
218 clustered with *E. fornicatus* in the PSHB clade 3A (Fig. 1). The COI sequences of 25 of the PSHB clade 3A individuals
219 from both locations in the Netherlands were identical to those from the Erfurt and Berlin interceptions, but not to those
220 from Italy and Poland interceptions (Fig. 1).

221

222 Discussion

223 Botanical gardens and greenhouses are hotspots for invasive species (Wang et al. 2015). The deliberate import of alien
224 plants might lead to the invasion of non-native plants (Hulme 2011) but might also lead to the introduction of associated
225 insects (Scott-Brown et al. 2018). Although introduced insects might suffer from the climatic conditions in the new
226 environment, greenhouses play an important role in helping them to adapt to the new environment, eventually aiding
227 the establishment and invasion of non-native insect species (Wang et al. 2015). Here we show an additional example of
228 a recent introduction of two non-native insect pests in botanical gardens of Europe.

229

230 Ambrosia beetles of the *Euwallacea fornicatus* species complex are invasive species introduced into various continents
231 but had not been detected in Europe. Here we describe the recent outbreaks of *E. fornicatus* in four tropical greenhouses
232 in Poland, Italy, and Germany. We reconstructed the invasion history and its invasion route. Molecular characterization
233 of 12 individuals from Poland and Italy showed that all individuals share the same mitochondrial haplotype, suggesting
234 that they were likely introduced from the same source population. The haplotype belongs to the Polyphagous shot hole
235 borer clade (Stouthamer et al. 2017) and most related to a haplotype found in Vietnam (Stouthamer et al. 2017; Fig. 1).
236 Since the haplotype was not described elsewhere, we could not determine the exact source population. In contrast, the
237 populations in Germany and the Netherlands were related to a different haplotype which has been previously described
238 in Taiwan (Stouthamer et al. 2017). This highlights that the cases from Germany likely resulted from an introduction
239 via one of the greenhouses of the commercial nursery in the Netherlands whereas the cases from Poland and Italy
240 resulted from an independent introduction event, likely from the same source population. The additional detection of *E.*
241 *perbrevis* in a greenhouse in the Netherlands highlights a third introduction event of a species which has not been found
242 elsewhere in Europe.

243

244 The outbreaks in the different localities were in different epidemiological phases: *E. fornicatus* in Poland was present in
245 a single sacred fig tree (*Ficus religiosa*) and not found in any other tree species in the same greenhouse, in Italy beetles
246 have been detected already in 28 different plants belonging to 21 species. It seems likely that the *E. fornicatus* was

247 introduced to Poland with an infested *F. religiosa* tree in 2016 and eradicated a few months later in the initial phase of
248 its establishment. In contrast, the outbreak in Italy was more advanced when it was discovered in 2020. The most
249 plausible explanation is that the ambrosia beetle was introduced with the *T. cacao* plant purchased in 2018 and
250 subsequently attacked other plant species in the greenhouse where the outbreak was detected two years later. In Erfurt
251 both infected trees of *Mangifera indica* and *Tectona grandis*, as well as most of the 136 infected trees in Berlin were
252 imported from the Netherlands. In both cases, the presence of the beetle was detected a few months after their
253 introduction.

254

255 Greenhouses might act as a springboard for non-native species if they are able to adapt and disperse to novel
256 environments (Wang et al. 2015). Although *E. fornicatus* might not be able to survive the outdoor conditions prevailing
257 in Poland, Germany and the Netherlands, Mediterranean conditions in Italy might allow an establishment of the beetles
258 in this area. Moreover, all affected greenhouses are surrounded by several native and non-native trees and shrubs,
259 known as potential hosts for *E. fornicatus*.

260

261 The occurrence of *E. fornicatus* in the greenhouse of a retailer in the Netherlands and especially the description of *E.*
262 *perbrevis*, which has not been described elsewhere in Europe highlights the need of more efficient examinations of
263 imported exotic plants prior to re-sale. While eradication may be relatively simple in a greenhouse environment, it
264 becomes much more problematic once a population is established outdoors. Therefore, we argue that surveillance
265 should be also intensified in tropical greenhouses in order to reduce the likelihood of an establishment in nature.

266

267 **Figures**

268 **Fig. 1** Phylogenetic tree based on partial (564 bp) mitochondrial *cox1* gene sequences representing the relation of the
269 individuals found in Europe (in bold and italics) with haplotypes described in other studies.
