Abstract

Objective: Carbapenem-resistant *Enterobacteriaceae* (CRE) are among the most severe threats to public and clinical health because of their high levels of resistance to various antibiotics. We assessed the efficacy of combination therapy with meropenem (MEM) and cefmetazole (CMZ) against Imipenemase (IMP)-producing CRE, using the checkerboard method and time-killing assay on 13 *Enterobacteriaceae* isolates harboring blaIMP-1 (4 *Enterobacter hormaechei*, 5 *Escherichia coli*, and 4 *Klebsiella pneumoniae* isolates) and 13 isolates harboring blaIMP-6 (8 *E. coli* and 5 *K. pneumoniae* isolates). Results: Minimum inhibitory concentrations (MICs) of MEM and CMZ ranged from 2 to 64 and 64 to 2048 µg/mL, respectively. Checkerboard method demonstrated the synergy of the MEM/CMZ combination in all the tested IMP-producing CRE isolates, and the time-kill assay indicated a bactericidal effect for both blaIMP-1 and blaIMP-6 positive CRE when MEM/CMZ combination was used. In vitro, the MEM/CMZ combination was potentially effective against IMP-1- or IMP-6-producing CRE. Further investigations including in vivo animal studies and clinical studies are warranted to corroborate the clinical utility of the novel combination therapy.

Introduction

Carbapenems are the last-resort antibiotics for the treatment of various infections caused by multidrug-resistant gram-negative bacteria. The wide global dissemination of carbapenem-resistant *Enterobacteriaceae* (CRE) is a serious threat to global public health and is a major concern to clinicians. Carbapenem resistance is mainly due to the production of carbapenemases whose genes are encoded on plasmids that are transmitted easily across bacterial species, which has resulted in the rapid spread of CRE worldwide [1].

Carbapenemases are categorized into mainly three classes (classes A, B, and D) of the Ambler β lactamase classification. The class A *Klebsiella pneumoniae* carbapenemases (KPCs) are one of the most prevalent carbapenemases. The class D OXA-48 carbapenemase producers have disseminated globally. Class B metallo-β-lactamases (MBLs) mainly comprise the VIM-, IMP-, and New Delhi Metallo-beta-lactamase (NDM)-types. Of these, NDM producers have rapidly spread worldwide since the first reports of their emergence in 2009 [1]. Despite their global dissemination, KPCs, OXAs, and NDMs are still not common in Japan, where IMP-1 and IMP-6 are the exclusively predominant carbapenemases [2, 3].

Treatment options for patients infected with carbapenemase-producing *Enterobacteriaceae* (CPE) are limited. For class A carbapenemases, such as KPC, a double-carbapenem therapy has been used [4]. Additionally, ceftazidime/avibactam combination, which is officially approved in Europe and the United States but not in Japan, has exhibited potent activity against OXA-48 producing gram-negative organisms [5]. However, MBL producers are resistant to these new treatments, and few studies have explored treatment strategies for MBL-producing *Enterobacteriaceae* [5, 6].

In a previous study, we demonstrated the *in vitro* efficacy of the combination of meropenem (MEM) and cefmetazole (CMZ) against KPC producers [7]. In this study, we investigated the *in vitro* activity of the MEM/CMZ combination therapy against IMP-producing CRE.

Methods

We used 13 *Enterobacteriaceae* isolates harboring *bla*_{IMP-1} (4 *Enterobacter hormaechei*, 5 *Escherichia coli*, and 4 *Klebsiella pneumoniae*) provided by Toho University, and 13 *Enterobacteriaceae* isolates harboring *bla*_{IMP-6} (8 *E. coli* and 5 *K. pneumoniae*) obtained in our previous CRE surveillance in Osaka, Japan [2].

We determined minimum inhibitory concentrations (MICs) of MEM and CMZ by the broth microdilution method based on CLSI document M07-A10 [8]. Briefly, we inoculated 5×10^5 colony forming units (CFU)/mL of bacterial suspension into BBL™ Mueller Hinton II Broth (Becton, Dickinson and Company, Sparks, MD, USA) and incubated at 35°C in ambient air for 18 h. MIC was defined as the lowest concentration of the tested antimicrobial that completely inhibited the growth of bacteria.

Details of the checkerboard method and time-killing assay have been presented previously [7]. In the checkerboard method, synergistic effect between MEM and CMZ against IMP-1 or IMP-6 producers was quantified by calculating the fractional inhibitory concentration (FIC) index. FIC index value ≤ 0.5 was defined as synergy, >0.5 to ≤ 4.0 as indifferent, and >4.0 as antagonistic. The assay was performed in duplicate. In case a synergistic effect was observed, MEM MIC fold-reduction was determined based on the lowest FIC index.

We conducted time-killing assays using the following two *E. coli* isolates: TUM13773 carrying *bla*_{IMP-1} and E109 carrying *bla*_{IMP-6}. During these assays, each isolate was incubated in Muller-Hinton II broth devoid of antibiotic (control) and with MEM, CMZ, or MEM/CMZ combination at the concentration of 25% of the MIC for individual isolates. CFUs of bacteria at 3, 6, 9, and 24 hours after beginning the treatment were counted. The averages of CFUs were calculated from duplicated assays. We defined an efficacy of the combination therapy as bactericidal when $\geq 3 \log_{10}$ CFU/mL reduction compared to the initial bacterial count was observed.

Results

MIC ranges of MEM and CMZ for isolates harboring *bla*_{IMP-1} were 2 to 8 µg/mL and 64 to 2048 µg/mL, respectively. Similarly, those harboring *bla*_{IMP-6} ranged from 16 to 32 µg/mL and from 64 to 1024 µg/mL, respectively (**Table 1**). No isolates were susceptible to both MEM and CMZ based on CLSI breakpoint values [9].

The checkerboard method showed that the combination of MEM and CMZ was synergistically active against all the tested IMP-producing CRE isolates (**Table 1**). MEM MICs in the combination decreased in the range from 1/4 to 1/32 of the MIC of MEM alone.

In the time-killing assays, the viable bacteria treated with each antibiotic alone regrew at 24 hours (**Fig. 1**). Contrarily, upon using the combination of 0.25× MIC MEM and 0.25× MIC CMZ, no growth was detected at 9 hours and 24 hours, indicating a bactericidal effect against the tested isolates.

Discussion

We demonstrated the *in vitro* efficacy of MEM in combination with CMZ against IMP-producing CRE isolates. This investigation was novel and was intended to corroborate the potency of CMZ, which may function as an antagonist of P-type carbapenemases. In addition to the double-carbapenem therapy [4] and ceftazidime/avibactam [5], newer β -lactamase inhibitors including relebactam (MK-7655), nacubactam (OP0595), zidebactam (WCK 5107), and vaborbactam (RPX7009) have been developed to treat CPE that produce serine-carbapenemases [10]. There are still no treatment options for infections caused by MBL-producing CRE.

CMZ is one of the established antimicrobials for which clinical experience of its use is being increasingly accumulated. It is a cephamycin antibiotic that is stable against extended-spectrum β -lactamases (ESBLs) [11], but is hydrolyzed by carbapenemases, including IMPs [12]. Presently, CRE isolates that produced IMPs were highly resistant to CMZ, with MICs ranging 64 to 2048 $\mu\text{g/mL}$. These findings may indicate a high affinity of CMZ to IMPs, and is consistent with our previous hypothesis that CMZ binds avidly to IMP-type carbapenemases and helps MEM exert its bactericidal activity, as seen in double-carbapenem therapy [4]. ESBL producing *Enterobacteriaceae* have globally disseminated [12] and CRE isolates co-harboring genes encoding ESBLs and carbapenemases have been previously described [13, 14]. Particularly, *bla*_{IMP-6} was reported to disseminate mainly through the horizontal transmission of the prevalent plasmid, pKPI-6, which simultaneously carries *bla*_{IMP-6} and *bla*_{CTX-M2} [15]. The CMZ combination therapy would be a ready-to-apply, cost-effective strategy for IMP-producing CRE, compared to the newer β -lactamase inhibitors.

Limitations

However, several limitations remain to be overcome prior to clinical use. First, the CMZ concentrations tested in this study exceed the serum levels attainable in humans. Second, as shown in our previous study [7], an inoculum effect may exist in this combination therapy, possibly resulting in treatment failure using a high bacterial inoculum. Third, various antimicrobial resistance mechanisms, such as AmpC-type beta-lactamases, efflux pumps, and porin loss, may influence the inhibitory activity of CMZ.

Despite these limitations, the collective data from this study demonstrate a preferential effect of MEM and CMZ when used in combination against IMP-producing CRE *in vitro*. Faced with the limited availability of new antimicrobials, the revived use of an existing antimicrobial agent could provide effective treatment. *In vivo* experiments as well as pharmacokinetic and pharmacodynamic studies are required before the clinical application of the new combination therapy.

CMZ, cefmetazole; MEM, meropenem. FIC index ≤ 0.5 was defined as synergy, >0.5 to ≤ 4.0 as indifferent, and >4.0 as antagonistic. MEM MIC fold-reduction by CMZ was calculated at the lowest FIC index.

Figures

a) IMP-1 producing *E. coli*

b) IMP-6 producing *E. coli*

Figure 1

Time kill curves for IMP-1- or IMP-6-producing *E. coli* isolates with MEM or CMZ only, or both MEM and CMZ. *E. coli* isolate TUM13773 carrying *bla*IMP-1 (a) and *E. coli* isolate E109 carrying *bla*IMP-6 (b) were incubated in Mueller Hinton II Broth (●) or supplemented with MEM (▲), with CMZ (◻) or with combination of MEM and CMZ (◻) at 37°C. All the antibiotics were used at concentrations of 25% of their MIC for individual isolates. Viable cells per milliliter before incubation and after incubation for 3, 6, 9, and 24 h were counted on Muller Hinton ◻ agar plates after overnight incubation at 37°C. Assays were performed in duplicate and the logarithm of the average CFU/ml was plotted.
