## Abstract

Background: Tumour subtype have a significant effect on bone metastasis in breast cancer, but population-based estimates of the prognosis of bone metastases at diagnosis of breast cancer are lacking. The aim of this study was to analyse the influence of tumour subtype and other factors in the prognostic and survival of patients with bone metastases of breast cancer. Methods: Using the Surveillance, Epidemiology, and End Results Program (SEER) data of 2012 to 2016 conducted a retrospective cohort study to investigate patients with bone metastases in breast cancer. Patients characteristic according subtypes were compared using chi-square, overall survival (OS), prognostic factor calculated using the Kaplan-Meier method and the Cox proportional hazards model. Results: A total of 3384 patients were included in this study. 63.42% were HR+/HER2-, 19.86% were HR+/HER2+, 9.34% were HR-/HER2-, and 7.39% were HR-/HER2+. Median OS for the whole population was 38 months, and 33.9% of the patients were alive at five-year. The median OS and five-year survival rate among the different molecular subtype of breast cancer patients are significant differences ( $p < 0.05$ ). Multivariate Cox regression analysis showed that age of 55-59 ( HR=1.270 ), black race ( HR=1.320 ), grade in III or IV ( HR=1.952 ), HR-/HER2- ( HR=2.727), lung metastases (HR=1.249), live metastases (HR=1.840), brain metastases (HR=1.812) only bone metastases ( HR=1.237) are independent risk factors of prognosis; married ( HR=0.812 ), HR+/HER2+ ( HR=0.618 ), HR-/HER2+ (HR=1.237), insurance ( HR=0.597 ) and surgery (HR=0.512) are independent protection factors of prognosis. Conclusions: There were substantial differences in OS according to tumour subtype. In addition to tumour subtype, other independent predictors of OS are age at diagnosis, race, marital status, insurance, grade, surgery and visceral metastases. Tumour subtype, as a significant prognostic factor, warrant further investigation. Keywords: Breast cancer, Bone metastases, Tumour subtype, Prognosis factor, Survival

## Background

Breast cancer is the second most common type of cancer in women and the second leading cause of cancer-related death in women, if untreated, the cancer can spread to other areas of the body. In

these patients, it is not the primary tumour, but its metastases at distant sites that are the main cause of death [1]. Approximately 5–10% of patients have distant metastases at the time of diagnosis[2, 3], bone is the most common site of metastasis in breast cancer patients, above 55% of breast cancer patients developing bone metastases[4]. Bone metastases are associated with lower survival in patients with advanced breast cancer and the 5-year cause-specific survival for these patients is only 24% to 39%[5]. Data showed that patients with breast cancer survive a median of 24–55 months after detection of bone metastases[6-8]. Breast cancer patients with bone metastases seem to have a longer survival than those with cancer in other metastatic sites[9].

According to the classification by hormone receptor status (HR) and human epidermal growth factor receptor-2 (HER2), breast cancer can be divided into HR+/HER2-, HR+/HER2+, HR-/HER2 and HR-/HER2+ [10]. After the molecular subtype of breast cancer were put forward, they quickly became the focus of research. The strong association of hormonal receptor status with bone metastasis was proposed early in 1991[11]. With a deeper understanding of the modulated genes and pathways in the various subgroups, it had become more evident that bone metastasis was most abundant among the hormonal receptor-positive subtype[12]. The researchers found that the clinical manifestations, pathological results, gene expression and prognosis of different subtype of breast cancer were very different. The relationship between molecular subtype and the patterns of distant metastases has been documented. Evidence had shown that bone metastases risk depends on breast cancer subtype, HR+ patients were more likely to have bone metastases[13]. The molecular differences in the tumour subtype were often accompanied by differences in clinical features and overall survival[10].

Notably, once tumour metastasizes to bone, it is incurable, bone metastases are associated with lower survival in patients with advanced breast cancer and an increased risk of serious complications during the patients' disease course. The consequences of bone metastases include reduced survival, morbidity, pain and reduced quality of life[14]. Therefore, in order to improve their survival time and outcome, it has great significance to identify the influencing factors of clinical prognosis in patients with bone metastasis of breast cancer. The aim of this study was to analyse the influence of tumour subtype and other factors in the prognostic and survival of patients who present with bone

metastases at the time of initial diagnosis of breast cancer.

## Methods

### **Data source and patient selection**

We abstracted data from the Surveillance, Epidemiology, and End Results (SEER) 18 registries research database. The SEER of the National Cancer Institute is a coordinated system of population-based cancer registries that collects cancer incidence and survival data from 18 geographic areas throughout the United States that together represent approximately 28% of the U.S. population and includes various diverse ethnic groups. A data use agreement submission was required to access the SEER Research Data File<sup>[15]</sup>. We submitted the data agreement form to the SEER administration, after acceptance of the agreement, the SEER\*Stat Version 8.3.5 software and data files were downloaded directly from the SEER website.

We used SEER\*Stat version 8.3.5 to generate a case listing. We extracted cases of woman aged 40-60 with brain metastases breast cancer diagnosed from 2012 to 2016. Selected this age group woman because the incidence of breast cancer rises after age 40, and the natural mortality of the elderly is high, age is the most important prognostic factor for bone metastases[16].

Patients diagnosed by either autopsy or death certificate were excluded. Patients must be have complete dates of survival month and the follow-up must be active. The analysis was restricted to a diagnosis confirmed by histopathology, and only duct, lobular and other carcinomas based on the primary site were included (International Classification of Disease for Oncology, Third Edition (ICD-O-3) codes 8500 to 8543). Tumour stage was registered according to the American Joint Committee on Cancer Staging System six edition. We excluded patients whose molecular subtype was unknown.

We generated a case listing with information on the following variables: year of diagnosis, age at diagnosis, race/ethnicity, marital status at diagnosis, grade, laterality, ICD-O-3 Hist/behav, AJCC Stage Group 6th ed, surgery prim site, bone/ lung/ liver \brain metastases, American Joint Committee on Cancer pathological stage, tumour subtype, cause-specific death classification, vital status, and survival (months).

## Statistical Analyses

Descriptive statistics were used to examine the following baseline characteristics of the breast cancer with bone metastases patients: year of diagnosis, age, race/ ethnicity, insurance, marital status, grade, surgery, laterality, histology, liver, lung, brain, bone only metastases, BCSS ( time from the breast cancer diagnosis to death due to breast cancer) and OS (the time from the breast cancer diagnosis to death due to any cause).

These variables were stratified by molecular subtype. *P*-values for comparing the frequency distributions among the subgroups were calculated using the chi-squared ( ) test. Within each variable, patients with unknown data were excluded from the comparative analysis. OS were used as the primary study outcomes, we used the Kaplan-Meier method to generate survival curves and analyse the differences between the curves using the log-rank test. A Cox proportional hazards regression was used to assess the independent association of several variables with OS. Hazard ratios (HR) and their 95% confidence interval (95%CI) were estimated using the Cox model. *P* value of 0.05 or less was considered statistically significant. All *P* values were 2-tailed. All statistical analyses were performed using SAS version 9.2 (SAS Institute Inc) and IBM SPSS version 23.0.

## Results

### Patient characteristics

A total of 3384 patients were diagnosed with bone metastases from breast cancer at initial presentation between 2012 and 2016 and were included in this study. 2146 patients (63.42%) were diagnosed with HR+/HER2- breast cancer, 672 patients (19.86%) were HR+/HER2+ breast cancer, 316 patients (9.34%) were HR-/HER2- breast cancer, and 250 patients (7.39%) were HR-/HER2+ breast cancer.

The demographic and clinical characteristics of the study based on breast cancer subtype showed in table1. Patients with bone metastases from HR-/HER2- breast cancer more likely were black race (*P* < 0.05), higher tumour grade (*P* < 0.05) and histology type classification of duct carcinoma (*P* < 0.05). HR-/HER2- breast cancer showed even higher incidence of combine with brain metastasis (*P* < 0.05), and more likely to die from breast cancer (*P* < 0.05), patients with bone metastases from HR-/HER2-

breast cancer HR-/HER2+ showed even higher incidence of combine with lung metastasis and liver ( $P < 0.05$ ).

#### Survival analysis

A median follow-up of 17 months (range, 1–60 months), 1315 deaths were reported (796 in the HR+/HER2- group, 198 in the HR+/HER2+ group, 224 in the HR-/HER2- group and 97 in the HR-/HER2+ group).

Median OS for the entire population was 38 months (95%CI: 35.89–40.11 months), and 33.9% of the patients (95% CI, 30.6–37.2%) were alive at 60 months, shown in Fig1. Analysis of OS according to tumour subtype showed significant differences with patients with bone metastases, the five-year survival rate was 32.7% for HR+/HER2-, 48.8% for HR+/HER2+, 8.6% for HR-/HER2- and 36.1% for HR-/HER2+. Patients with bone metastases of HR-/HER2- breast cancer experiencing the shortest survival (median OS: 11 months; 95% CI: 9.9–12.1 months), whereas patients with HR+/HER2+ breast cancer experiencing the longest survival, median OS was 52 months (95% CI was not estimable;  $P < 0.001$ ).

The impact of the presence of metastases at each individual visceral site on OS is shown in Fig.3. Patients with lung metastases had significantly shorter survival (median OS: 23 months; 95% CI: 19.98–26.02 months) as compared with patients without liver metastases (median OS: 42 months; 95% CI: 39.77–44.23 months;  $P < 0.05$ ; Fig. 3a). Patients with liver metastases (median OS: 22 months; 95% CI: 19.10–24.86 months) versus no lung metastases (median OS: 44 months; 95% CI: 41.14–46.86 months;  $P < 0.05$ ; Fig. 3b). Patients with metastases to the brain (median OS: 14 months; 95% CI: 11.08–40.10 months) and those with metastases to the brain and other sites (median OS: 40 months; 95% CI: 37.80–42.20 months;  $P < 0.001$ ; Fig. 3c). A similar finding was seen for with metastases to the bone only (median OS: 46 months; 95% CI: 42.56–49.44 months) and those with metastases to the bone and other sites (median OS: 24 months; 95% CI: 24.61–26.38 months  $P < 0.05$ ; Fig. 3d).

Unadjusted models for the overall patient population were consistent with log-rank analysis (except laterality ) and revealed that patients who were older, black race, single, uninsured, duct histology, III

or IV Grade, primary bilateral breast cancer, triple-negative subtype, Visceral metastases and those who did not receive surgery to the primary tumour had shorter OS (Table 2).

Multivariate Cox analyses confirmed that age of 55-59 (vs. age of 40-44, HR=1.270, 95%CI: 1.032-1.563), black race (vs. white race, HR=1.320, 95%CI: 1.129-1.543), grade in III or IV (vs. grade in I, HR=1.952, 95%CI: 1.485-2.564), HR-/HER2- (vs. HR+/HER2-, HR=2.727, 95%CI: 2.268-3.278), lung metastases (vs. no, HR=1.249, 95%CI: 1.036-1.506), liver metastases (vs. no, HR=1.840, 95%CI: 1.511-2.240), brain metastases (vs. no, HR=1.812, 95%CI: 1.463-2.245), only bone metastases (vs. no, HR=1.237, 95%CI: 1.024-1.465) are independent risk factors of prognosis; married status (vs. single, HR=0.812, 95%CI: 0.701-0.940), insurance (vs. no, HR=0.597, 95%CI: 0.466-0.764) and surgery (vs. no, HR=0.512, 95%CI: 0.438-0.599) are independent protection factors of prognosis.

Histology, primary laterality did not reach significance with this test. Multivariate Cox model is shown in Table 3.

## Discussion

Bone metastases are the most common distant metastatic site in breast cancer, severe complications, low quality of life and poor prognosis in patients, the rate of survival significantly decreased are often associated with the occurrence of bone metastases[14]. Our study analyzed recently available data on the subtype in bone metastatic breast cancer patients from the SEER registries, in an attempt to analyze differences in the effects of the breast cancer subtype and other factors on the patient prognosis.

Bone metastasis is most abundant among the HR+ subtype, the distribution of our study patient tumour subtype is similar to other studies in the published literature[12,17,18]. Our studies have identified the subgroups of patients with HR+/HER2- breast cancer is the most prone to bone metastasis, secondly is HR+/HER2+ breast cancer. HR-/HER2- has a particular propensity to metastasize to the brain and lung, brain metastasis is more common than for the other subtype, and the bone metastasis is relatively less likely to occur, this is consistent with previous research[19]. This may be due to different molecular subtype of breast cancer lead to different metastasis sites due to their special molecular biological characteristics.

The median OS for the entire cohort was 38 months of the patients, this is similar with Kuchuk 's study that from 294 electronic records of metastatic breast cancer patients were reviewed ,they found the median OS from bone metastasis diagnosis is 40 months in bone metastasis patients[20].The median OS is 46 months for patients with only bone metastases ,those with bone and other sites metastases is 24 months in our study is similar to the survival reported by previous authors in recent years[8]. Study of 815 patients with de novo or recurrent metastatic breast cancer and identified that patients with visceral metastases as well as those with multiple metastatic sites had worse OS, findings consistent with our results[21]. The five year survival rate is 33.9% which is similar with previous studies that shown 24-39% of patients alive in five year after diagnosis of bone metastases[5]. It may be due to the fact that the subjects of this study are menopausal women, the age of the previous subjects is unlimited, the proportion of elderly patients is large and the prognosis is poor, and with the improving of treatment methods in recent years, the prognosis of the patients has been improved.

Our study shown the five-year survival rate of HR+/HER2+ patients is the highest, reached 5.6 times of HR-/HER2- patients. Patients with HR+/HER2+ breast cancer had the longest median survival period. However, our study have shown that the incidence of bone metastasis in HR-/HER2- breast cancer was low, but patients with HR-/HER2- tumour had the worst prognosis. And OS in patients with HR-/HER2- breast cancer were significantly lower than those in patients with other molecular subtype, with the shortest median survival time. The large difference in prognosis observed across all tumour subtype confirms that breast cancer is a heterogeneous disease, even in the specific group of patients with bone metastases. The improvements in OS seen in HER2+ patients could be explained in part by the efficacy of HER2-targeted agents. In Dawood' s large-scale, randomized study , there were 2019 women with metastatic breast cancer that showed HER2+ patients who received trastuzumab had improved prognosis compared with HER2- patients[22]. However, the HR-/HER2- is an invasion subtype, with the characteristics of rapid progress, strong aggressiveness, high degree of malignancy, easy occurrence of distant metastasis, rapid relapse[23-25]. Therefore,

Our study includes tumour subtype as a prognostic factor and provides evidence of a clear association of age, race, marital status, insurance, tumour grade, histology, subtype, and visceral metastases in

bone metastasis patients with OS. This was similar with previous study. The Denmark data were population-based health registries, included all women in diagnosed during 1999–2011 with regional or stage II/III breast cancer, showed predictors of recurrence, metastases, and mortality included age, hormone receptor status, and stage at diagnosis[28]. Ahn ' study showed ER- negative and bone metastasis combined with visceral metastasis is a risk factor for OS [8]. Iqbal J' study showed US women diagnosed with invasive breast cancer, the survival varied by race and ethnicity, black women are more likely to die due to breast cancer within 7 years compared with non-Hispanic white or Asian women[29]. The protective effect of marriage for survival, that can be explained by patients can gained better economic resources and greater social support in marriage[30]. Although some factors have been found in previous studies, no covariates have been adjusted for other factors, or fewer covariates have been adjusted. We used a Cox proportional regression model by adjusting for all the factors and demonstrated the tumour subtype were prognosis factors.

We acknowledge that the study has some limitations. SEER database could not know the expression status of ki-67, the ki-67 index value is a prognostic factor in primary breast cancer and is a proliferation marker that also distinguishes between luminal A and luminal B breast cancer[26]. Breast cancer is generally divided into luminal A and luminal B , according to HR  $\square$ HER2 status and ki-67 in the course of clinical diagnosis and treatment[27]. This may contribute to some disparities between our investigation and clinical applications. We do not have information with regards to radiotherapy or systemic treatments of this cohort, which may contribute to some of the differences observed in survival according to prognostic variables. Addition,the pathological data could not be centrally reviewed and were collected from different local pathology laboratories.

## Conclusions

In conclusion, our results revealed a relatively good prognosis of bone metastasis, the median OS for patients was 38 months, 33.9% of patients were alive at five years. Subtype is a significant prognostic factor, the prognosis of patients with HR-/HER2- subtype is the worst, median OS only 11 months. Except tumour subtype, race, marital status, insurance, grade, site of metastases, surgery are

independent predictors of OS.
