Abstract

**Background:** The aim of this study was to determine in-hospital mortality in patients presenting with acute respiratory syndrome corona virus 2 (SARS-CoV-2) and to evaluate for any differences in outcome according to gender.

**Methods:** Patients with SRS-CoV-2 infection were recruited into this retrospective cohort study between February 26 and September 8, 2020 and stratified according to the gender.

**Results:** In total of 3360 patients (mean age 44 ± 17 years) were included, of whom 2221 (66%) were male. The average length of hospitalization was 13 days (range: 2–31 days). During hospitalization and follow-up 176 patients (5.24%) died. Mortality rates were significantly different according to gender (p= <0.001). Specifically, male gender was associated with significantly greater mortality when compared to female gender with results significant at an alpha of 0.05, LL = 28.67, df = 1, p = 0.001, suggesting that gender could reliably determine mortality rates. The coefficient for the males was significant, $B = 1.02$, $SE = 0.21$, $HR = 2.78$, $p< .001$, indicating that an observation in the male category will have a hazard 2.78 times greater than that in the female category. Multivariate logistic regression confirmed male patients admitted with SARS-CoV-2 had higher cumulative all-cause in-hospital mortality (6.8% vs. 2.3%; adjusted odds ratio (aOR), 2.80; 95% (CI): [1.61 - 5.03]; p < 0.001).

**Conclusions:** Male gender was an independent predictor of in-hospital death in this study. The mortality rate among male SARS-CoV-2 patients was 2.8 times higher when compared with females.

**Highlights**
- In-hospital mortality in SARS-CoV-2 male patients are 2.8 times higher when compared to females.
- Average length of ICU stay was longer in males SARS-CoV-2 patients

**Background**

In-hospital mortality in patients affected with SARS-CoV-2 reportedly ranges from 17–77%. [1, 2, 3] Recent data from 38 countries suggests that mortality may be up to 1.7 times higher males than in females. [4] The prevalence of SARS-CoV-2 infection was also reportedly higher in males compared with females. [5, 6] Previous studies in patients admitted with MERS and SARS-CoV have also reported a higher mortality amongst males [7, 8], who appear to be more susceptible to infection than females. [9] One contributory factor may be smoking history which is more prevalent amongst males. [10] The lower incidence of SARS-CoV-2 in females may also be related to oestrogen-related protection and X-linked gene-related immune responses. [11, 12]

**Methods**
All patients aged 18 and older diagnosed with SRS-CoV- between February 26 and September 8, 2020 were included both Kuwaitis and non-Kuwaitis. All data were abstracted from electronic medical records of two tertiary care hospitals in Kuwait: Jaber-hmed Hospital and AlAdnan General Hospital. A positive RT-R swab from the nasopharynx confirmed SRS-CoV-2 infection. All patients were treated with a standard universal protocol according to The Ministry of Health, Kuwait. The standing committee for health coordination and medical research at the Ministry of Health in Kuwait approved the study protocol and accepted the request for waiver of the consent (Institutional the requirement of informed consent).

The primary endpoint was mortality due to COVID-19, as specified by ID 10 code U07.1. The collected data comprised socioeconomic factors, co-morbidities, clinical presentation, test results, and ICU and hospital admission duration. For data entry, an electronic case-record form (CRF) was employed.

**Statistical Analysis**

Descriptive statistics were used to summarise clinical data. Categorical variables were presented as frequencies and percentages, and the Pearson's X2 test used to analyse them. Continuous variables were summarized as mean and standard deviation.

A multivariable logistic regression was used to determine the impact of gender on all-cause mortality. Input variables included gender, age, neutrophils, platelet count, and haemoglobin were used to adjust the odds ratios (oRs) for in-hospital all-cause mortality outcome. A Cox proportional hazards model was utilised to see if gender had a major impact on the risk of mortality. The significance threshold was set at p<0.05. R statistical packages [14] and SPSS version 27 (SPSS, Chicago, IL, US) were used to perform statistical analyses.

**Results**

A total of 3360 study participants were included. The mean age was 44 ± 17 years, and 2221 (66%) of the patients were males. The median length of hospital stay was 13 (range 2–31) days. In this cohort 176 patients (5.24%) died with significantly higher mortality in males (p = < 0.001). [Table 1].

When compared to females, males had significantly higher hemoglobin (132 vs 177 g/L; p<0.001), white blood cell (8.1 vs 7.3 10⁹/L; p<0.001) and neutrophil (57 vs 54 /ml; p<0.001) counts, prothrombin (15.6 vs 14.6 sec; p = 0.016) and activated partial thromboplastin (37.8 vs 35.4 sec; p = 0.047) times, as well as international normalized ratio(1.2 vs 1.1 10⁹/L; p = 0.016) ([Table 2]).

Mortality was higher in individuals with lower haemoglobin (124, 22.4%) when compared to individuals with higher haemoglobin (52, 0.82 %; p 0.001). Individuals with a haemoglobin level less than 100 g/L had a greater cumulative all-cause in-hospital mortality than those with haemoglobin levels higher than 100 g/L (22.4 % vs. 0.8 %; R, 0.29; 95 % CI: [0.18–0.46]; p 0.001). In-hospital mortality was associated with a higher neutrophil count [aOR,1.17; 95% CI:(1.14–1.20, p 0.001) and a lower platelet count [aOR,1.00;
95% I:(1.00–1.00, p = 0.005). With respect to all-cause cumulative in-hospital mortality, age had no significant impact among the groups (aOR, 1.00; 95% CI [0.98–1.02]; p 0.960). [Table 3] Male gender had a large impact on cumulative all-cause in-hospital mortality (6.8% vs. 2.3%) [R, 2.80; 95% CI: [1.61, 5.03]; p 0.001). [Table 3].

Kaplan-Meier survival probability plots were used for the analysis based on gender. Each plot depicts the survival probabilities of various groups over time. Male sex was related to increased mortality (Kaplan-Meier survival probability plot). The model's results were significant and could not be explained by an alpha of 0.05, LL = 28.67, df = 1, p = 0.001, showing that gender could appropriately estimate the risk of mortality. The coefficient for male gender was significant, B = 1.02, SE = 0.21, HR = 2.78, p.001p < .001, indicating that male gender was associated with risk of mortality 2.78 times greater than female gender at any given point in time. Gender was observed to be important in predicting in-hospital mortality among SRS-oV-2 patients in this study. [FIGURE 1]

**Discussion**

The main finding of our study is that male gender is an independent predictor of in-hospital mortality in patients diagnosed with SARS-CoV-2. Specifically, mortality in males with SARS-CoV-2 was 2.8 times higher than in females. Moreover, average length of ICU stay was longer in males. However, females were on average older than male patients. Although older in age, especially middle age and above, had higher mortality, this did not reach statistical significance. A higher neutrophil count and a lower platelet count had a significant impact on in-hospital mortality. The mortality rate was also seen higher in those with lower hemoglobin levels, which has been reported previously. [15] Reasons for these findings most probably relate to severity of infection and the extent of immune response that could be associated with increase in mortality.

One reason for higher mortality observed in males could be the higher prevalence of ACE-2 in the lungs. [16] Oestrogen-related protection in females may suppress SARS-CoV-2, thereby leading to lower mortality. [17, 18] The male to female ratio observed in our study was higher than that in prior studies (1.5:1). [19, 20] The significance of gender is equally important as other risk factors in SARS-CoV-2 infection. [21] Several studies have reported higher mortality from SARS-CoV-2 in males. For example, in 144,279 patients in England and Wales significantly higher mortality was observed in males. [22] Similar findings were reported in Europe and Wuhan. [23, 24] In addition, a study from Italy reported lower mortality in hospitalized females, but similar mortality among males and females in critically ill SARS-CoV-2 patients. [25] while more critically ill male patients were seen in a study conducted in Europe. [26]

Delays in admission have also contributed to an increased rate of mortality in male patients in the setting of SARS-CoV-2. [27] Younger males and elderly females were the most vulnerable in terms of mortality. [28] In a systematic review and meta-analysis, it was evident that both alcohol consumption and smoking increase mortality in males and females. [29]
Our study does have some limitations. First, the study is retrospective limiting causal inference while unmeasured confounding factors, such as clinical co-morbidities and medications, could have affected the outcomes. Also, since our study included all positive COVID-19 patients in Kuwait it likely includes mainly milder cases of the disease.

**Conclusions**

This study demonstrated that gender is an independent predictor of in-hospital mortality in SARS-CoV-2 patients with males 2.8 times more likely to die than females. Despite males having a shorter overall hospitalization than females males spent a greater proportion of time in intensive care unit than females. More prospective studies are required to better understand sex-related morbidity and mortality.
