Abstract

Severe bacterial infections (SBI) have become less frequent in children with sickle cell disease (SCD) in the last decades. However, because of their potential risk of SBI, they usually receive empirical therapy with broad-spectrum antibiotics when they develop fever and are hospitalized in many cases. We performed a prospective study including 79 SCD patients with fever [median age 4.1 (1.7–7.5) years, 78.5% males; 17 of the episodes were diagnosed with SBI and 4 of them were confirmed] and developed a risk score for the prediction of SBI. The optimal score included CRP > 3 mg/dl, IL-6 > 125 pg/ml and hypoxemia, with an AUC of 0.91 (0.83–0.96) for the prediction of confirmed SBI and 0.86 (0.77–0.93) for possible SBI. We classified the patients in 3 groups: low, intermediate and high risk of SBI. Our risk-score based management proposal could help to safely minimize antibiotic treatments and hospital admissions in children with SCD at low risk of SBI.

Introduction

The incidence of bacteremia and other severe bacterial infections (SBI) in children with sickle cell disease (SCD) has decreased in recent years in high-income countries^{1–4}. However, because of their potential risk of SBI, they usually receive empirical therapy with broad-spectrum antibiotics when they develop fever, and are hospitalized in many cases⁵. A frequent use of broad-spectrum antibiotics entails complications such as potential side effects or infections by multidrug-resistant bacteria, in addition to increasing healthcare costs. The aims of this study were to develop a risk score for the prediction of SBI in children with SCD and fever and to propose an alternative strategy of management according to the risk group of each patient. This proposal could help to safely minimize the use of broad-spectrum antibiotics and hospital admissions in those patients at low risk of SBI.

Material And Methods

We performed a prospective study, from June 2015 to June 2018, including children with SCD and fever at the Hospital General Universitario Gregorio Marañón in Madrid, a reference center for patients with SCD in Spain. Exclusion criteria included age older than 18 years, hematopoietic stem cell transplantation, incomplete diagnostic tests and patients whose parents or legal guardians did not sign the informed consent form. The study received approval from the Institutional Review Board.

The following studies were performed on all study participants upon arrival at the hospital: blood tests [complete blood count, biochemistry, C reactive protein (CRP), procalcitonin and 10 proinflammatory cytokines], blood cultures and nasopharyngeal samples for viral detection by a multiplex-PCR assay. Other diagnostic tests and the patients' management were performed according to national guidelines⁵. Confirmed SBI (CSBI) was defined as a severe infection with the identification of a microorganism in a normally sterile site and possible SBI (PSBI) as a clinical syndrome compatible with SBI but not microbiologically confirmed. For the purposes of this study, pneumonia without a bacterial confirmation

and acute chest syndrome (ACS) were considered PSBI. Hereinafter, SBI will be used to refer to CSBI and PSBI together. More detailed data about study setting and definitions are described in Supplemental data.

Statistical analysis

Continuous variables were compared with T test or Mann-Whitney U test, whereas χ^2 test or Fisher's exact test were used for categorical variables. A p value < 0.05 was considered significant. A multivariate logistic regression predictive model was used to design a risk score, including significant variables from the univariate analyses and from previous studies^{4,6} and transforming quantitative variables into binary variables, with the most sensitive cut-offs. The best predictive model was chosen using the Akaike information criterion. Coefficients from the multivariate regression model were converted into integer "points" to create the score. Receiver operating characteristic (ROC) curves were generated. Sensitivity, specificity, positive predictive values (VPP) and negative predictive values (NPV) were calculated for different cut-off values and the last two also according to various possible prevalence rates (PR) of SBI. Predictive margins were used to report probabilities with 95% confidence intervals of CSBI and PSBI according to the risk score.

Results

Seventy-nine febrile episodes were included in the study (flow diagram in Fig. 1). Median age of the patients was 4.1 (interquartile range 1.7–7.5) years and 78.5% of the episodes occurred in males. Most children had been diagnosed by newborn screening (91.1%), were appropriately immunized (88.6%) and were receiving penicillin prophylaxis (98.7%).

Seventeen episodes were diagnosed with SBI: 4 CSBI [3.2%; 2 catheter-related bacteremia caused by *Staphylococcus aureus* and *Enterobacter cloacae*, respectively, one *Streptococcus pneumoniae* bacteremic pneumonia (serotype 9N) and one *Escherichia coli* urinary tract infection (UTI)] and 13 PSBI [16.5%; 12 pneumonia/ACS and one bacterial-viral coinfection (*E. coli* UTI and influenza B)]. A virus was detected in 41 (51.9%) of the respiratory samples, being influenza (A or B) and rhinovirus the more frequently detected viruses, in 23.3% and 20.9% of the cases, respectively. Baseline characteristics of patients, clinical and laboratory parameters during the febrile episode and comparisons between patients with and without SBI are summarized in Table 1. Most of the patients were treated as inpatients (81%) and received at least one dose of antibiotic (96.2%). Three patients (3.8%) needed PICU admission, and no patient died. Patients with SBI presented more frequently with hypoxemia, had significantly higher inflammatory parameters and longer duration of fever and hospitalization.

The variables included in the initial predictive model were: hypoxemia < 92%, hemodynamic instability, central venous catheter (CVC), initial white blood count > 15 x 10⁹/L, neutrophils > 10 x 10⁹/L, CRP > 3 mg/dl, procalcitonin > 0.6 ng/ml and IL-6 > 125 pg/ml. The best predictive model included PCR > 3 mg/dl (2 points), IL-6 > 125 ng/ml (1 point) and hypoxemia (1 point). The area under the ROC curve for this

Loading [MathJax]/jax/output/CommonHTML/jax.js

model was 0.91 (95% CI 0.83–0.96) for the prediction of CSBI and 0.86 (0.77–0.93) for PSBI. Table 2 shows the performance of the predictive model for CSBI and PSBI according to different cut-off points, with the best sensitivity and NPV for ≥ 1 point and the best specificity and PPV ≥ 3 point. Based on these cut-off points, the individual risk of a patient can be divided in 3 groups: low risk (0 points), moderate risk (1–2 points) and high risk (3–4 points). The individual risk score of patients in our cohort and the proportion of SBI in each group are also detailed in Table 2. The probability of SBI according to the risk score is shown in Fig. 2. Our management proposal, according to the risk group of each patient, is described in Fig. 3.

Discussion

In this prospective study we propose a risk-score based strategy of management for children with SCD and fever, according to their risk group of SBI, with the final goal of minimizing antibiotic exposure in those patients at low-risk. In order to avoid the possibility of not giving antibiotics to a patient who might potentially need them, we included PSBI (mostly cases of pneumonia or ACS) in addition to CSBI.

Most children included in this study had been diagnosed by newborn screening, were completely immunized and receiving penicillin prophylaxis. We found a low rate of CSBI, with a higher proportion of PSBI (mainly pneumonia/ACS), in agreement to other studies from high-income countries^{1,3,7}. Several studies had previously reported different predictors of bacteremia and other severe infections in patients with SCD, including elevated CRP, procalcitonin, WBC and neutrophils, toxic appearance, vomiting and long-term CVC^{2,4,8,9}. IL-6 has also been recently described by our group as a marker of CSBI in these patients⁶. Other studies had also reported hypoxemia and elevated WBC or neutrophils as predictors of pneumonia or ACS^{3,10}.

We designed a risk score including 3 variables (CRP, IL-6 and hypoxemia), assigning 2, 1 and 1 points to each variable, respectively. An individualized score of < 1 point (0 points) had the highest sensitivity and NPV, while a score of ≥ 3 points had the highest specificity and PPV, both for CSBI and for PSBI. We divided the children in 3 groups: low risk (0 points), moderate risk (1–2 points) and high risk (3–4 points) of SBI. In our cohort, 38 (48.1%) patients would have been classified as low risk, without any case of CSBI

agnosed with “mild ACS” because of an infiltrate in the chest

X-ray without hypoxemia; he only had one day of fever and bocavirus was detected in respiratory samples). However, in the group of high risk, we found 9/9 (100%) SBI cases, 3 of them (33.3%) CSBI.

Based on our findings, we propose a different management according to the risk of SBI of each patient, described in Fig. 2 (excluding patients with toxic appearance and those incompletely immunized, non-adherent to penicillin prophylaxis and CVC carriers, due to their higher risk of SBI). We recommend that in patients classified in the low-risk group the use of empirical broad-spectrum antibiotics could be avoided, while those with moderate risk should receive at least one intravenous dose of a long-acting and broad-spectrum antibiotic such as ceftriaxone. All these low-risk children could be managed as outpatients, with blood cultures done and close follow-up within 24 hours, as long as they do not present other complications (e.g. significant anemia or severe pain) and have the possibility of quick access to the hospital in case of clinical worsening. However, patients with high risk of SBI should be hospitalized and receive broad-spectrum antibiotics, at least until blood cultures remain negative after 48–72 hours of incubation. According to our data, this approach would potentially prevent almost a half of antibiotic treatments and the majority of the hospital admissions.

This study has several limitations. Most importantly, the sample size is relatively small, with few cases of confirmed bacterial infection. However, this prospective study was carried out in a reference center for SCD in Spain and this cohort may be quite representative of children with SCD in high-income countries, in which the incidence of SBI is low. Secondly, ACS cases were classified as PSBI due to the difficulty of excluding a bacterial pneumonia in these cases. Finally, IL-6 may not be available in all centers, although its use as a biomarker has become widespread recently due to anti-IL-6 use in SARS-CoV-2 pandemic.

In conclusion, we developed a score to estimate the risk of SBI (confirmed or possible, such as ACS) applicable to SCD children who are completely immunized, receive adequate prophylaxis and are trained to detect warning signs of severity. This proposal could help change the current practice of administering antibiotics to all children with SCD and fever into a different strategy of management, according to the risk group of each patient. Further studies are needed to validate this score and to confirm these findings. This may result in safely minimizing the use of broad-spectrum antibiotics and hospital admissions in SCD patients at low risk of SBI.

Abbreviations

SBI	Severe bacterial infection
SCD	Sickle cell disease
CRP	C-reactive protein
IL-6	Interleukin 6
CSBI	Confirmed severe bacterial infection
PSBI	Possible severe bacterial infection
ACS	Acute chest syndrome
ROC	Receiver operating characteristic
PPV	Positive predictive value
NPV	Negative predictive value
PR	Prevalence rate
UTI	Urinary tract infection
CVC	Central venous catheter
