Research
Abstract

**Background:** Previous studies have suggested a correlation between alterations in the routine blood check markers and cognitive impairment.

**Objective:** We aimed to explore the relationship between routine blood parameters and cognitive impairment.

**Methods:** In this retrospective case-control study, 8,025 people over 60 years of age were enrolled from 51 community health centers in Luohu District of Shenzhen City from 2017 to 2018. According to the mini-mental state examination (MMSE) score and educational level, participants were divided into a cognitive impairment group (n=385) and normal cognitive function group (n=7,640). Nonparametric test, chi-square test, and binary logistic regression were applied to analyze the data.

**Results:** Compared to the normal cognitive function group, the lymphocyte-to-monocyte ratio (LMR), packed-cell volume (PCV), and platelet count (PLT) in the cognitive impairment group were significantly lower (7.26 [5.50,8.81] vs. 7.45 [5.80,9.35]; 40.1 [36.65,42.95] vs. 40.5 [37.7,43.1]; 216 [190,258] vs. 228 [196,261], p<0.05, respectively), while the monocyte count and mean corpuscular hemoglobin concentration (MCHC) were higher (0.31 [0.25, 0.38] vs. 0.3 [0.24, 0.37]; 336 [330, 343] vs. 335 [328, 342], p<0.05, respectively). Additionally, MCHC [odds ratio (OR):1.011, 95% confidence interval (CI) :1.001–1.021, p= 0.033] and PCV [OR: 0.993, 95% CI: 0.987–0.999, p = 0.033] were independently associated with cognitive impairment.

**Conclusion:** The alterations in some routine blood check parameters, including reduced LMR, PCV, and PLT, and elevated monocyte count and MCHC, may be associated with cognitive impairment.

**Background**

Dementia is becoming increasingly common in the aging population. Alzheimer’s disease (AD), the principal type of dementia, has a devastating impact on human health and the economy worldwide [1]. Over the past decades, many scientific experiments have been conducted to explore the pathology of AD and to discover novel treatments. AD is characterized by neuronal and synaptic degeneration, together with an extensive number of amyloid-beta (Aβ) plaques and neurofibrillary tangles, which may occur before the appearance of symptoms [2]. Screening for reliable and suitable biomarkers that can be used before the clinical manifestations become apparent has been an urgent issue for AD investigators. Compared to cerebrospinal fluid, which is now widely used as a diagnostic source to aid the clinical diagnosis of AD, peripheral blood samples are easier to collect and comparatively less invasive. As highly invasive procedures are not appropriate for screening, accumulating evidence shows that besides the well-known markers, Aβ and tau protein in blood, many routine peripheral blood parameters may be potentially useful as novel biomarkers to reflect the prognosis of AD and other neurological disorders. However, results have been inconsistent and lack reproducibility [3–5]. It has been shown that the mean platelet volume (MPV) and platelet distribution width (PDW) are decreased in patients with mild cognitive
impairment (MCI) and AD. Lower hemoglobin levels are associated with cognitive impairment, and elevated red cell distribution width (RDW) is related to a reduced brain volume and cognitive dysfunction [6, 7]. Here, we investigate further the association between alterations in the peripheral blood parameters and cognitive impairment among the elderly in Shenzhen City, Guangdong, China.

**Material And Method**

**Study population**

From 2017 to 2018, we enrolled 9,411 participants aged over 60 years old from 51 community health centers in Luohu District of the third affiliated hospital of Shenzhen University Medical College, Shenzhen City. A total of 8,025 participants was enrolled based on the following inclusion criteria: age > 60 years, intact visual and auditory function, and ability to complete the mini-mental state examination (MMSE). Excluded were persons with acute or chronic infectious diseases, malignant tumors, hematologic system diseases, or severe liver and kidney diseases that may affect the routine blood indicators. Subjects with MMSE score \(\leq 21\) (for subjects with an education level of primary school or below) or MMSE score \(\leq 24\) (for subjects with an education level of secondary school and above) were considered to have cognitive impairment.

Participants were divided into a cognitive impairment group (n = 385) and a normal cognitive function group (n = 7640) (Fig. 1). Written informed consent was obtained, which included permission for the analysis and data sharing. This study was approved by the Independent Ethics Committee of the third affiliated hospital of Shenzhen University Medical College.

**Clinical variables**

The routine laboratory parameters were measured, including white blood cell (WBC), lymphocyte count, neutrophil count, monocyte count, lymphocyte%, neutrophil%, monocyte%, red blood cell count (RBC), hemoglobin (HGB), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), packed-cell volume (PCV), platelet count (PLT), MPV, PDW, and RDW, consisting of red cell distribution width standard deviation (RDW-SD) and red cell distribution width coefficient variable (RDW-CV). The neutrophil-to-lymphocyte ratio (NLR), lymphocyte to monocyte ratio (LMR), and platelet-to-lymphocyte ratio (PLR) were also calculated.

**Statistical analysis**

Data obtained from participants in the cognitive impairment group and the normal cognitive function group were compared with respect to MMSE score, laboratory results, and including. The Kolmogorov-Smirnov test was used to assess the normality of continuous variances. Participants’ characteristics were summarized as means (standard deviation) or medians (first quartile, third quartile) for continuous data (dependent on their distribution), and counts (proportions) for categorical variables. Continuous data were analyzed using the Mann-Whitney test if there was a skewed distribution. Categorical data were analyzed using the chi-square test. A binary logistic regression analysis was performed for statistically
different indicators. All statistical analyses in this study were performed using SPSS software (version 26.0; IBM SPSS Inc., Chicago, IL, USA), and statistical significance was set at $p < 0.05$.

**Results**

In total, 385 elderly participants with cognitive impairment (median age: 68 [64, 74] years, 203 women [52.70%]) and 7,640 elderly participants with normal cognitive function (median age: 67 (63, 71) years, 4,408 women [57.70%]) were included in this study. between the two groups.

Blood parameters were significantly different between the cognitive impairment group and normal cognitive function group (Table 1): LMR (7.26 [5.50, 8.81] vs. 7.45 [5.80, 9.35], $p < 0.05$); PCV (40.10 [36.65, 42.95] vs. 40.50 [37.70, 43.10], $p < 0.05$); PLT (216 [190, 258] vs. 228 [196, 261], $p < 0.05$); monocyte count (0.31 [0.25, 0.38] vs. 0.30 [0.24, 0.37], $p < 0.05$); and MCHC (336 [330, 343] vs. 335 [328, 342], $p < 0.05$). The binary logistic regression analysis showed that MCHC (odds ratio [OR]: 1.011, 95% confidence interval [CI]: 1.001–1.021, $p = 0.033$) and PCV (OR: 0.993, 95% CI: 0.987–0.999, $p = 0.033$) were independently associated with cognitive impairment (Table 2).

### Discussion

We evaluated the association between alterations in routine blood parameters and cognitive impairment among 8,025 elderly patients. Decreased LMR, PCV, and PLT, and increased monocyte count and MCHC were associated with cognitive impairment among the elderly participants, and may be useful for the early evaluation and diagnosis of AD.

Platelets play important roles in neurodegenerative, cardiovascular, and psychiatric diseases, and have been widely used as a peripheral model to study the molecular mechanisms of AD [8, 9]. Platelets are the primary source of circulating amyloid precursor protein (APP), and APP may represent the major source of Aβ (the cleavage product of APP) detected in the whole blood [10]. It has been demonstrated that APP is expressed at similar levels in the platelets and brain [11]. Previous studies have suggested that platelet APP metabolism may promote Aβ accumulation in the brain [12]. A recent study identified the essential functions of the APP family with regard to normal hippocampal function and circuits during development.
One study showed that the platelet level was statistically lower in patients with AD, which is consistent with our findings [9]. Some studies have also shown that platelets can accumulate and release neurotransmitters, such as serotonin, glutamate, and dopamine. Glutamate is a pivotal excitatory neurotransmitter in the central nervous system, which is related to cognitive function [14]. It has also been verified that the tau protein, another important pathophysiological component of AD, is present in platelets [15, 16]. In addition, it has been shown that platelet size reflects platelet activity, which is related to a variety of proinflammatory diseases. MPV, the most commonly used measure of platelet size, is an early marker of activated platelets, and has different trends in different diseases [17]. PDW, another platelet index, can also indicate variations in the platelet size. Although some previous studies have indicated that MPV and PDW were decreased in MCI and AD patients [18, 19], we did not find significant differences in MPV and PDW levels between these two groups (Table 1).

In our study, there were significant differences in the monocyte count and LMR between the two groups (Table 1). The inflammatory response is known to be a key factor in the generation of Aβ plaques and neurofibrillary tangles, which initially execute protective functions but eventually lead to neural degeneration and the manifestations of AD [20]. Blood-derived leukocyte subpopulations, including lymphocytes, monocytes, and neutrophils, have been identified in the brains of patients with AD and in corresponding animal models. Monocytes can reflect the innate immune inflammatory status, and chronic inflammation might cause an increase in the monocytes circulating in the blood. Subsequently, high monocyte levels may activate glial cells to secrete cytokines such as IL-1 and TNF-α that damage the integrity of the blood-brain barrier (BBB), which is critical in the pathogenesis of AD [21]. Increasing evidence has shown that the serum levels of neopterin, which is produced by activated monocytes, are related to their capacity to release reactive oxygen species; these are higher in AD patients than in age-matched healthy controls [22–24]. In line with several studies, decreased lymphocyte count in the cognitive impairment group was observed compared to the normal cognitive function group, although the difference was not significant in our study [4, 21, 25]. The decrease in the lymphocyte count, as part of the immune regulatory barrier, could reflect the body’s stress response. TNF-α, released by microglia, is able to recruit lymphocytes from the peripheral circulation across the BBB into the central nervous system, which leads to a reduction in their numbers in the peripheral circulation. Furthermore, it has been shown that increased telomerase activity in lymphocytes can result in reduced lymphocyte proliferation in patients with AD [26, 27]. With regard to neutrophils, the increased neutrophil count is usually related to the occurrence, progression, and severity of inflammation. The depletion or inhibition of neutrophils reduces the pathogenesis and cognitive impairment of AD in mouse models of cognitive dysfunction [28]. In recent years, an increasing number of studies have focused on NLR, a combined inflammatory biomarker that could have an advantage over a single leukocyte subtype and relatively higher clinical significance. The potential role of NLR in AD was first investigated by Kuyumcu et al., who found that NLR was significantly higher in AD patients compared to controls [29]. Several studies have also reported that elderly people with AD have a higher NLR than healthy controls, although we did not find a significant difference in the present study [4, 29, 30]. In summary, it was thought that the NLR was not specific enough to be used as a definitive diagnostic tool for AD or MCI [20].
According to our results, the PCV (Hct) level was decreased in the cognitive impairment group, which is consistent with a previous study [7]. PCV is viewed as a simple indicator of the number and volume of RBCs, which is an important indicator for diagnosing anemia. Although the erythrocyte count (4.55 vs 4.56) and hemoglobin level (137 vs 138) were not significantly different between the two groups, they were lower than those in the normal cognitive function group. AD is a complex multifactorial disease, and anemia is known to be associated with AD. Studies have suggested that lower hemoglobin levels are associated with poor cognition [31, 32]. Several mechanisms might explain this phenomenon.

Hemoglobin is a heme-containing protein that binds to oxygen, carbon monoxide, and nitric oxide. Erythrocytes are the most common location of hemoglobin. It is well known that the brain oxygen supply is mainly derived from the oxygen carried by RBCs. Numerous studies have revealed that exposure to hypoxia induces amyloidogenic processing of APP, leading to the accumulation of amyloid-β peptides in the brain [33, 34]. Notably, in AD, microglia defend the neurons by surrounding senile plaques to protect the brain and decrease damage. It has been demonstrated that hypoxia compromises the mitochondrial metabolism of microglia via hypoxia inducible factor 1 (HIF1) in AD [35]. One more possible explanation is that iron, an important component of hemoglobin which is involved in the transport of oxygen, accumulates in tissue stores and is not adequately mobilized in AD [36, 37]. Faux et al. found significantly greater prevalence of abnormally high serum ferritin together with lower plasma iron levels and transferrin saturation in AD, which is in line with studies that showed that iron metabolism was disrupted in cortical neurons in mouse models [7]. Additionally, studies have indicated that hemoglobin is a normal component of nerve cells, and plays a role in intraneural oxygen homeostasis. Moreover, decreased hemoglobin levels were associated with decreased cortical thickness in the frontal, temporal, parietal, and occipital regions, which are vital areas related to cognitive function [38]. Besides hemoglobin, it has been suggested that complement/complement receptor 1 (CR1) mediation is the predominant mechanism of Aβ capture by erythrocytes [39].

We found that the MCHC level in the cognitive impairment group was higher than that in the normal group (1.28 [0.90,1.81] vs. 1.38 [0.98,1.98], $p = 0.003$), which is consistent with the results of a previous study [18]. MCHC indicates the amount of hemoglobin per unit volume, and correlates the hemoglobin content with the volume of the cell. In fact, MCHC levels have always been controversial among different studies, and several studies have demonstrated that decreased MCHC is related to cognitive impairment, while others have claimed that MCHC levels were not correlated with memory and cognitive abilities [40]. Therefore, it is difficult to explain the elevation of MCHC according to the current literature.

**Limitations**

First, it would be more accurate if we combined the MMSE with neuroimaging markers to evaluate cognitive function. Second, we did not rule out some chronic comorbidities, including hypertension, hyperlipidemia, and diabetes mellitus, which are important confounding factors that may affect blood cell profiles. Although we found that the differences in the blood parameters are associated with cognitive impairment, it remains unclear whether these changes are the cause or the result.
Conclusion

Our study suggests that biomarkers in routine blood samples may be related to cognitive impairment, including a decrease in the LMR, PCV, and PLT, and elevation in the MONO and MCHC. Further studies are needed to investigate the pathophysiological and clinical significance of these changes in blood cells to offer new insights for the prevention and treatment of AD.
