Assessing production efficiency by farm size in Rwanda: a zero-inefficiency stochastic frontier approach

Abstract
This study investigates the relationship between farm size and technical efficiency for maize production in Rwanda. Since levels of technical efficiency tend to vary considerably across farms in sub-Saharan Africa, with a mixture of both inefficient and fully efficient farms, the use of the conventional stochastic frontier method is not appropriate. In this paper, we apply a zero-inefficiency stochastic frontier method that manages both efficiency and inefficiency in the studied sample. The average technical efficiency of maize farms for the full sample is estimated at 0.64, demonstrating that maize output can be improved by approximately 36% without increasing the proportion of farm inputs used. Regarding the relationship between farm size and technical efficiency, the study results show a positive relationship between farm size and technical efficiency for maize production in Rwanda. Thus, the enforcement of land reforms such as land consolidation and enhanced aggregate productivity growth are needed. The results also indicate that education, cooperative membership, extension services, access to credit, off-farm income, land tenure, and livestock ownership have significant and positive effects on technical efficiency.

Keywords: technical efficiency; farm size; stochastic production frontier; zero-inefficiency; Rwanda

1. Introduction
Increased agricultural productivity has been identified as a major solution that can lead to improved food security, poverty reduction, and economic growth in Sub-Saharan Africa (SSA) (Julien et al. 2019). In recent decades, agrarian policies adopted in most SSA countries have supported the promotion of agricultural technologies and the efficient use of scarce land resources to achieve sustainable farm yields (Ali and Deininger 2015). Agricultural production across SSA countries is largely dominated by small-scale farming (Julien et al. 2019). In particular, Rwanda, the most densely populated country in Africa, has an average landholding level of only approximately 0.72 hectares per household (Ali and Deininger 2015). Moreover, smallholder farming in Rwanda is usually not capital intensive, i.e., most smallholder farm operators do not use farm machinery in their agricultural activities and are characterized by low crop productivity (Ali et al. 2015).

Recently, issues related to small-scale farm sizes, land fragmentation, and low crop productivity in Rwanda have been a priority to policymakers, research institutions, and nongovernment organizations (Ali and Deininger 2015). Khataza et al. (2019) indicated that the efficient management of scarce land resources devoted to farming activities constitutes an essential instrument towards the improvement of agricultural productivity and food security. In an attempt to achieve food security, the Rwandan government has adopted a land consolidation program to reallocate fragmented small-scale farm plots to form large-scale parcels for more rational landholding (Ansoms et al. 2008). These institutional changes are expected to increase economies of scale (Ali and Deininger 2015).

An enduring debate in the agricultural economics and rural development literature concerns the relationship between farm size and agricultural productivity. This relationship has significant implications for agricultural and land policies (Khataza et al. 2019; Rada and Fuglie 2019; Zhong et al. 2019). However, empirical evidence from previous studies suggests that it
remains unclear whether small-scale farms are more productive than large-scale farms (Barrett et al. 2010; Gautam and Ahmed 2019; Julien et al. 2019; Khataza et al. 2019; Kimhi 2006; Rada and Fuglie 2019). Numerous studies have confirmed inverse relationships between farm size and various agricultural productivity measures, such as technical efficiency (TE) and total factor productivity (TFP). In the context of agricultural production in SSA, such inverse relationships have recently attracted considerable attention from policymakers and researchers, mainly due to their controversial implications for land reforms and agricultural policies (Desiere and Jolliffe 2018). In this regard, the existence of an inverse relationship between farm size and productivity implies that land redistribution should be considered an appropriate land reform that can improve the managerial performance (i.e., TE) of farmers and hence agricultural productivity (Julien et al. 2019). On the other hand, empirical studies have found a positive relationship between farm size and productivity (Kimhi 2006; Muyanga and Jayne 2019; Xin et al. 2016), suggesting that land consolidation can be considered an appropriate policy means to improve productivity (Desiere and Jolliffe 2018).

In the literature, variations in empirical findings on the relationship between farm size and productivity are mainly attributed to the use of different analytical approaches (Barrett et al. 2010; Gautam and Ahmed 2019; Julien et al. 2019; Khataza et al. 2019; Muyanga and Jayne 2019; Zhong et al. 2019). Some empirical studies have applied the ordinary least squares (OLS) model. In contrast, other studies have used frontier-based approaches such as the stochastic frontier (SF) model to examine the relationship between farm size and productivity. Typically, these conventional approaches assume that all farms in a sample are inefficient, implying that the probability of observing fully efficient farms is zero (Abdulai and Abdulai 2016). Nevertheless, evidence from the literature indicates the presence of both inefficiency and full efficiency among farmers in SSA (Abdulai and Abdulai 2016; Theriault and Serra 2014). Thus, the use of the
conventional SF model without accounting for both inefficiency and full efficiency may result in biased estimates, which may also lead to inappropriate policy making (Abdulai and Abdulai 2016). Kumbhakar et al. (2013) introduced a zero inefficiency stochastic frontier (ZISF) model to manage this assumption of inefficient behavior.

This study uses the ZISF model to investigate the relationship between farm size and TE for maize production in Rwanda. In Rwanda’s context, only three studies have attempted to investigate the relationship between farm size and productivity (Ali and Deininger 2015; Ansoms et al. 2008; Byiringiro and Reardon 1996). However, none of those studies apply frontier-based approaches that are known to manage productive inefficiency. Our study contributes to the existing literature by demonstrating the application of the ZISF model to examine the farm size-productivity relationship.

The remainder of this paper is structured as follows. Section 2 presents the background on land problems in Rwanda. Section 3 presents the methods used with a detailed discussion of the conventional SF and ZISF models. Section 4 provides a description of the data and summary statistics. Section 5 presents the empirical results and a discussion. The final section concludes with a summary of the study’s findings and policy implications.

2. Background on land and productivity in Rwanda

Land remains a valuable asset that determines to an exceptional level the social status and the economic well-being of households in Rwanda and most parts of sub-Saharan Africa (Holden and Otsuka 2014; Muchomba 2017; Pritchard 2013). Land tenure reforms have been given considerable attention in the Poverty Reduction Strategy Papers of several African countries (Place 2009). In particular, the secured land property rights are among the top priorities of the
development agenda of the Rwandan government because, conceptually, improving it may foster agricultural investment and production growth (Bambio and Bouayad Agha 2018).

2.1. Land related issues in Rwanda

Land fragmentation and land scarcity are becoming significant threats to the improvement of agricultural production and food security in Rwanda (Ntihinyurwa et al. 2019). In particular, Rwanda is the most densely populated country in Africa, and a large number of the population (about 83%) live in rural areas (Pritchard, 2013).\(^1\) Rwanda’s population pressure has also resulted in smaller plots and fragmented landholdings (Bizoza 2014). Place (2009) argues that land fragmentation constitutes a significant obstacle to agricultural development because it hinders agricultural mechanization tools such as tractors and harvesters. Land fragmentation can also discourage the adoption of irrigation technologies and other long-term investments on land that are only profitable on a larger scale (Tran and Vu 2019). Given that plot size has been diminishing over the years, land distribution in Rwanda is also highly unequal with a large portion of land being owned by a minority of wealthier elite including politicians, business people, and civil servants from urban areas (Musahara and Huggins 2005; Pritchard 2013).

Inequality in land distribution is a major policy issue for the government of Rwanda, as it may influence land-related conflicts and poverty (Musahara 2006).

Bizoza (2014) also noted that population pressure had induced shifts in land use, resulting in the cultivation of fragile marginal land on steep slopes and deforestation. In general, the Ministry of Agriculture and Animal Resources (MINAGRI) acknowledges that considerable land

---

\(^1\) According to the fourth Integrated Household Living Conditions Survey, Rwanda has a population density of about 462 people per square kilometer.
degradation due to soil erosion has significantly reduced agricultural production (Minagri 2018).

Recently, soil conservation efforts have focused on the building of terraces, hedges, and agroforestry (Pritchard 2013).

2.2. The relevance of farm size-productivity relationship in the context of Rwanda

Rwandan economy relies heavily on the agriculture sector, with about 75% of the economically active population employed in agriculture (World 2018). The subsistence-based agriculture sector of Rwanda is dominated by small-scale farms (Ali and Deininger 2015).

Moreover, the high population growth exerts severe pressure on arable land, which is a constraint to agricultural productivity (Julien et al. 2019). Consequently, the current strategic plan for agricultural transformation has a target of addressing the issue of low crop productivity through crop intensification and land consolidation programs (Ansoms et al. 2008).

Regarding the above context of Rwanda’s agriculture, empirical studies investigating the relationship between farm size and productivity are relevant. The conclusions about the category of land size (i.e., whether small-scale or large-scale) that is more efficient and productive, would provide useful insights to land reforms and agricultural policies directed towards the increase of agricultural productivity and food security. For instance, efforts to promote land consolidation should be prioritized if large farms are found to be more efficient than their smaller counterparts (Khataza et al. 2019).

3. Methodology
According to Farrell (1957) classical proposition, TE is one of two components of total economic performance and allocative efficiency (Coelli et al. 1998). Typically, in the literature, two empirical approaches have been broadly used to estimate TE. The first is DEA, which is a nonparametric approach involving the use of linear programming techniques (Khataza et al. 2019; Liu et al. 2017). Although efficiency estimation using DEA does not impose a functional form on the data, this approach fails to effectively address statistical noise that is likely to affect the accuracy of estimates (Khataza et al. 2019; Liu et al. 2017). Alternatively, parametric models such as the SF model are also widely used to estimate TE. Coelli et al. (1998) suggest that the SF approach, which involves econometric methods, is the most appropriate approach to TE analysis in agricultural production studies, as the SF model can address statistical noise (outliers). Furthermore, the SF model allows for statistical tests of hypotheses regarding parameter estimates and for the measurement of TE across farms of different sizes (Julien et al. 2019). Consequently, we adopt the SF model in the present study.

3.1. Stochastic production frontier model

The general form of the conventional SF model is as follows:

\[ Y_i = f(X_i; \beta) \cdot \exp(\varepsilon_i), \quad i = 1, 2, \ldots, N. \]  

(1)

where \( Y_i \) represents the output of farm \( i \), and \( f(\cdot) \) is the production function (e.g., Cobb–Douglas or translog). \( X_i \) denotes a vector of inputs, and \( \beta \) is a vector of unknown parameters to be estimated. Note that composite error term \( \varepsilon_i \) is made up of two components:

\[ \varepsilon_i = v_i - u_i. \]  

(2)

2 The TE of a farm reflects its ability to achieve the maximum output possible from a given set of inputs.
where $v_i$ is a random error term representing statistical noise due to unobserved factors beyond the producer’s control (e.g., weather fluctuation) and measurement errors. As noted by Coelli et al. (1998), the random error component is assumed to be normally distributed with a mean of 0 and constant variance of $\sigma_v^2$, i.e., $[v_i \sim N(0, \sigma_v^2)]$. The second component is nonnegative inefficiency error term $u_i$, which is assumed to follow a positive truncated normal distribution (i.e., $u_i \geq 0$) with a mean of $\mu$ and variance of $\sigma_u^2$, i.e., $u_i \sim N^+(0, \sigma_u^2)$.

The specification of technical inefficiency ($u_i$) can then be written as:

$$u_i = z_i \delta + \omega_i,$$

where $z_i$ denotes a set of farm- and household-specific covariates, and $\delta$ is a vector of parameters to be estimated.

### 3.2. Zero inefficiency stochastic frontier model

Following Kumbhakar et al. (2013), the ZISF production model is specified as follows:

$$ZISF \rightarrow y_i = x_i' \beta + v_i \quad \text{with probability } p,$$

$$y_i = x_i' \beta + (v_i - u_i) \quad \text{with probability } (1 - p)$$

where $y_i$ represents the output of farm $i$, $x_i$ is a vector of inputs, $\beta$ is a vector of unknown parameters to be estimated, $p$ is the probability of a farm being fully efficient, and $(1 - p)$ is the probability of a farm being inefficient. The composed error term in the ZISF model is given by $v_i - u_i[1 - 1(u_i = 0)]$ where $p = 1(u_i = 0)$.

The density function of the convoluted error term of the ZISF model is defined as:

$$f(\varepsilon|x) = \left(\frac{p}{\sigma_v}\right) g \left(\frac{\varepsilon}{\sigma_v}\right) + (1 - p) \left[\frac{2}{\sigma} g \left(\frac{\varepsilon}{\sigma}\right) G \left(-\frac{\lambda \varepsilon}{\sigma}\right)\right]$$

where $g$ and $G$ are the normal probability density and normal cumulative distribution functions, respectively, $\sigma^2 = \sigma_u^2 + \sigma_v^2$, and $\lambda = \sigma_u / \sigma_v$. 
For the estimation of the inefficiency function in the ZISF model, we adopt the approach developed by Jondrow et al. (1982), which postulates that the conditional density function of inefficiency $u$ given $\varepsilon$ is zero with probability $p$ and truncated normal $N_{+}(\mu_*, \sigma_*^2)$ with probability $1 - p$. This function is expressed as:

$$f(u|\varepsilon) = \frac{g[(u-u_*)/\sigma_*]}{\sigma_*, G(-\varepsilon\lambda/\sigma)}$$  \hspace{1cm} (6)

where $\mu_* = -\varepsilon\sigma_*^2/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. From the specification in Equation (6), the conditional mean estimator for inefficiency in the ZISF model is given by:

$$E(u|\varepsilon) = (1 - p)\frac{\sigma\lambda}{1+\lambda^2} \left[ \frac{g(-\lambda\varepsilon/\sigma)}{G(-\lambda\varepsilon/\sigma)} - \frac{\lambda\varepsilon}{\sigma} \right]$$  \hspace{1cm} (7)

Here, the measurement procedure entails the replacement of unknown parameters with their maximum likelihood (ML) estimates, and error term $\varepsilon$ should be replaced by its residuals $\hat{\varepsilon}_i$. In addition, inefficiency in the ZISF model can be estimated by constructing the posterior estimates of inefficiency, which are expressed as:

$$\tilde{u}_i = (1 - \hat{p}_i)\hat{u}_i$$  \hspace{1cm} (8)

where $\hat{p}_i$ denotes the posterior estimate of the probability of full efficiency, which is written as:

$$\hat{p}_i = \frac{(\hat{p}_i/\hat{\sigma}_v)g(\hat{\varepsilon}_i/\hat{\sigma}_v)}{(\hat{p}_i/\hat{\sigma}_v)g(\hat{\varepsilon}_i/\hat{\sigma}_v) + (1 - \hat{p}_i)(2/\hat{\sigma})g(\hat{\varepsilon}_i/\hat{\sigma})G(-\hat{\varepsilon}_i/\hat{\sigma}_0)}$$  \hspace{1cm} (9)

These posterior estimates of inefficiency are influenced by farm and household characteristics.

To test for zero inefficiency, we use the pseudolikelihood ratio (PLR) test. The PLR test is represented as $PLR = -2(L_N - L_{ZI})$ where $L_N$ denotes the log-likelihood of the normal linear model estimated using OLS and $L_{ZI}$ denotes the log-likelihood of the ZISF model. As noted by Kumbhakar et al. (2013), the PLR test has an asymptotic distribution that constitutes a 50:50 mixture of inefficient $\chi^2_0$ and fully efficient $\chi^2_1$ distributions. In testing for zero inefficiency, the rejection of the null hypothesis of full efficiency (i.e., $H_0: p = 1$) indicates the presence...
efficiency in the ZISF model and of inefficiency in the conventional SF model (Abdulai and
Abdulai 2016).

3.3. Empirical specification

The empirical specification of SF models typically uses Cobb-Douglas or translog
functional forms. The Cobb-Douglas functional form is the most commonly used in the literature
due to its simplicity and consistency with key properties of production economic theory (Julien et
al. 2019). However, the Cobb-Douglas form requires that the partial elasticities of production and
returns to scale have the same value across all data points (Julien et al. 2019; Khataza et al.
2019). In contrast, the translog does not impose restrictions on partial elasticities of production or
returns to scale. Nevertheless, it fails to maintain consistency with the key properties of
production economic theory such as monotonicity and quasi-concavity (Julien et al. 2019). Thus,
to ensure flexibility in the estimated parameters and consistency with production economic
theory, we adopt the Cobb-Douglas functional form, which is specified as follows:

\[
\ln Y_i = \beta_0 + \sum_{j=1}^{4} \beta_j \ln X_{ij} + (v_i - u_i),
\]

\[
u_i = \sum_{d=1}^{11} \delta_d Z_{id} + e_i
\]

where \(Y_i\) is the production output of maize, \(X_{ij}\) is the \(j^{th}\) input of the \(i^{th}\) farmer, and \(\beta_j\) and \(\delta_d\)
are the unknown parameters to be estimated. We include four inputs, namely, land, labor,
fertilizer, and seeds.

Additionally, we include eleven determinants of technical inefficiency (\(Z\)) based on
relevant literature and data availability. These variables include age, gender, household size,
education, cooperative membership, access to credit, extension services, slope, land tenure, off-
farm work, and livestock ownership.
4. Data and summary statistics

4.1. Data and variable definition

The data used in this study are cross-sectional data collected through a household survey conducted in the Eastern Province of Rwanda from July to August 2019. A representative sample of this study consists of 351 household farmers randomly selected from three districts, namely, the Bugesera, Kirehe, and Nyagatare districts of the Eastern Province of Rwanda. This sample was drawn using a multistage sampling technique. First, in consultation with the Ministry of Agriculture and Animal Resources (MINAGRI), three districts were purposively selected based on their intensive maize production levels. In the second stage, four administrative sectors were randomly selected from each district due a predominance of maize farmers. In the third stage, a random sample of respondents was selected from each sector for personal interviews. Based on the list of farmers obtained from each extension officer at the sector level, a total of 1197 individual farm household units were counted and recorded in all 12 sectors. Due to limited resources and time, 34 respondents were randomly selected from each sector, resulting in a total sample of 408 household farmers. However, after cleaning the collected data, we ended up with a total sample of 351 household farmers.

Respondents were interviewed using a structured questionnaire by trained and experienced research assistants. The survey collected detailed information on maize production outputs and on inputs used in the production process during the 2018–2019 crop season. Information on the socioeconomic characteristics of the households and on institutional and farm-specific characteristics was also collected.

Table 1. Description of variables used in the analysis

<tr>
<td></td>
<td>slopes and 0 otherwise</td>
</tr>
<tr>
<td>Livestock</td>
<td>Amount of livestock owned in tropical livestock units (TLUs)</td>
</tr>
</tbody>
</table>

Note: TLUs across various categories of livestock are computed as follows: 0.7 for cows; 0.45 for heifers; 0.1 for goats; 0.1 for sheep; 0.01 for chicken; and 0.2 for pigs (Zeweld et al. 2015).

In general, agricultural production in Rwanda is not capital intensive because most of the farmers do not use agricultural machinery (e.g., tractors) in their farming activities. Indeed, the variable inputs included in our analytical model are land, labor, fertilizer, and seeds (see Table 1). The land input is measured as the total farm size in hectares (ha) planted with maize during the
2018–2019 crop season. Labor input (i.e., hired and family labor) used to perform all farm
operations during the 2018–2019 crop season is measured in person-days per ha. Typically, in the
majority of Sub-Saharan African countries, the labor force consists of men, women, and children.
Hence, following Khataza et al. (2017), labor is defined in terms of adult equivalent units using
the following conversion factors: one adult male (at least 15 years of age, working on a full day-
basis) represents one person-day. An adult female working on a full day-basis represents 0.8
person-days, and one child (5–14 years) working for a full day represents 0.5 person-days (Julien
et al. 2019; Khataza et al. 2017). Fertilizer input is measured as the total quantity of di-
ammonium phosphate and urea in kilograms per ha applied on the farm during the 2018–2019
crop season. Seed input is expressed as the quantity in kilograms per ha of maize seeds used in
farm production during the 2018–2019 cropping season.

Furthermore, the explanatory variables used in the analysis as the determinants of
technical inefficiency are presented in Table 1. Household demographic variables such as age,
education, household size, and gender may influence the TE. For instance, higher levels of
education are expected to improve farmers’ managerial performance which can also enhance
TE’s level (Julien et al. 2019). A dummy variable for cooperative membership is included to
assess the effect of cooperatives on TE. Based on the empirical evidence from previous studies
(Abdul-Rahaman and Abdulai 2018; Helfand and Levine 2004; Mar et al. 2018; Mwalupaso et al.
2019), we expect the participation in farmers’ cooperatives to have a positive effect on TE. Other
institutional factors, such as extension services and access to credit, are considered to be an
important determinant of farm TE. They are both expected to be positively correlated with TE.
The variable slope is expressed as a dummy variable equal to one if the farm is located on a steep
slope and zero otherwise. Typically, the slope variable is expected to be negatively correlated
with the TE due to the evidence that steep slopes tend to face problems related to irrigation
development, mechanization, and soil erosion (Julien et al. 2019). The remaining explanatory variables are land tenure, off-farm income, and livestock ownership.

4.2. Summary statistics

Table 2 presents the mean values and standard deviations of all variables used in the present study for the full sample and across each of the three considered farm size categories. Following Byiringiro and Reardon (1996) suggestions, the three categories of farm size in Rwanda are defined as (1) small-scale farms with land area of less than 1 ha; (2) medium-scale farms with land area of 1–2.5 ha; and (3) large-scale farms with land area of over 2.5 ha. The summary statistics reported in Table 2 show considerable differences between the three farm size categories. Indeed, the average yield is highest (2285 kg/ha) for large-scale farms while small-scale farms have the lowest average yield (1766 kg/ha). In terms of production inputs used per hectare, the average amount of fertilizers used on large-scale farms is higher than that used on medium- and small-scale farms by approximately 9.3% and 22.5%, respectively. Similarly, on average, large-scale farms use more maize seeds per hectare than medium- and small-scale farms. Regarding the average use of human labor, large-scale farms use labor more intensively than medium- and small-scale farms.

In our sample, the socioeconomic characteristics of households vary significantly across farm size categories. The summary statistics reported in Table 2 indicate that educational attainment is generally low (i.e., below six years of primary education). By comparison, large-scale farmers have completed more education than medium- and small-scale farmers. The majority of households (69%) in the study area have male heads, and their average age is approximately 47 years. On average, farmers with large-scale farms secure greater access to extension services and credit than their counterparts with medium- and small-scale farms (see
Moreover, membership in agricultural cooperatives is higher among large-scale farmers (62%) than for medium- (53%) and small-scale farmers (36%). In addition to the above variables, other variables such as livestock ownership, land tenure, slope, and off-farm income exhibit clear differences between the three farm size categories. Differences in socioeconomic and farm characteristics can be significant sources of dissimilarity in farm managerial performance (i.e., TE) across farm size categories (Julien et al. 2019; Muyanga and Jayne 2019).

5. Results and Discussion

Table 3 presents parameter estimates of the production frontier and inefficiency effect functions of the conventional SF and ZISF models. Table 3 also reports the results of the model diagnostics. The PLR test result is statistically significant at the 1% level, implying the presence of both inefficient and fully efficient farms in our sample. Additionally, the probability of being fully efficient is 12.1% and statistically significant at the 1% level. Results of maximum likelihood estimates of the coefficients for the stochastic production function indicate that the parameters for all input variables are statistically significant, and the signs of all input coefficients are positive, as expected, for both the conventional SF and ZISF models (see Table 3).

Notes: ***, **, * indicate levels of significance at 1%, 5%, and 10%, respectively. A negative coefficient sign for variables of the technical inefficiency effect function implies that the variable has a positive effect on TE and vice versa.
5.1. Partial production elasticities and returns to scale

In our empirical analysis, we estimate partial production elasticities to assess the responsiveness of maize yields to varying levels of each of the classical inputs, ceteris paribus. The estimated coefficients of the Cobb-Douglas production function are directly read as partial production elasticities for the inputs (Coelli et al. 1998). The results listed in Table 3 indicate that maize yields are more responsive to fertilizer inputs than to other production inputs (i.e., seeds, land, and labor). In the ZISF model, the partial production elasticity value of 0.311 calculated for fertilizer input implies that a 1% increase in fertilizer use per hectare would increase maize yields by approximately 0.31%, ceteris paribus. The strong influence of fertilizer input observed is not surprising due to the benefits of using fertilizer to enhance crop yields (Hurley et al. 2018) and corroborates the findings of Anang et al. (2017), Zhuo and Shunfeng (2008), and Makombe et al. (2017). Furthermore, the corresponding estimates of partial production elasticities for seeds, land, and labor are 0.228, 0.178, and 0.164, respectively.

The study considers the estimation of returns to scale (also referred to as the elasticity of scale), which evaluates the proportional change in output that results from a unit proportional change in all inputs combined (Coelli et al. 1998). The elasticity of scale, which is computed by summing the partial production elasticities, is equal to 0.881. This result suggests that maize farms operate under decreasing returns to scale, implying that a 1% increase in all inputs can result in a less than 1% increase in output.

5.2. Determinants of technical efficiency

Table 3 provides the coefficient estimates of factors affecting technical inefficiency. We analyzed socioeconomic, institutional, and farm-specific variables. The results of the ZISF model indicate
that seven variables, including education, cooperative membership, extension services, access to credit, off-farm income, land tenure, and livestock ownership, are statistically significant. The negative sign of the coefficient of variables for the technical inefficiency effect function suggests that the variable has a positive effect on TE, and the reverse is correct for the positive sign of the coefficient.

Education appears to be positively associated with TE, as expected. Gebremedhin et al. (2009) also found that education has a significantly positive effect in improving the TE of smallholder farmers in Ethiopia. As a plausible explanation for this finding, better educated farmers are likely to have better access to necessary information on the state of agricultural technologies and on the optimal use of farming practices than their counterparts (Liu et al. 2017).

Access to agricultural extension services also appears to have a significantly positive influence on TE. This finding is consistent with the work of Binam et al. (2004) and Ngango and Kim (2019). Indeed, the delivery of agricultural extension services is expected to encourage farm operators to learn and adopt better farming practices (Theriault and Serra 2014). The coefficient of access to credit is negative and statistically significant at the 1% level, implying that access to credit enhances the level of TE. Binam et al. (2004) also noted that smallholder farmers in the slash and burn agriculture zone of Cameroon with access to credit are more technically efficient than their counterparts without access to credit. Moreover, the negative and statistically significant coefficient of the land tenure variable suggests that land ownership is positively associated with TE. Livestock ownership is found to have a statistically significant and positive effect on TE. As expected, cooperative membership is also positively associated with TE. The negative and statistically significant coefficient of off-farm income suggests that farmers with off-farm income tend to exhibit higher levels of TE.
5.3. Technical efficiency estimates

The summary statistics of TE estimates for the full sample and for the three farm size groups are reported in Table 4. The average TE score for all households in the sample is estimated at 0.64. As we have estimated the output-oriented TE, the mean TE score of 0.64 implies that the maize output can be improved by approximately 36% without increasing the proportion of farm inputs used. This finding is comparable to those of previous studies that have attempted to analyze the TE of the agricultural production sector in Africa. For instance, Julien et al. (2019) applied the random parameter stochastic production frontier model to assess farm performance in Uganda and found a mean TE level of 0.64. Khataza et al. (2019) also report a mean TE of 0.60 for a sample of maize producers in Malawi.

Results for the relationship between farm size and TE are also presented in Table 4. The results indicate that on average, large-scale farms appear to be more technically efficient than both medium- and small-scale farms. Indeed, the average TE score for large-scale farms is 79.7% while the average TE scores for medium- and small-scale farms are 65.1% and 47.6%, respectively. These results denote a positive relationship between farm size and TE in Rwanda’s maize production sector.

6. Conclusions and policy implications

In this study, we assessed the relationship between farm size and technical efficiency for the maize production sector in Rwanda. In addition, we analyzed potential determinants of technical efficiency for maize production systems in Rwanda. We employed the ZISF model for analytical purposes and a cross-sectional dataset consisting of a sample of 351 household farmers operating in the Eastern Province of Rwanda. The ZISF model is more advantageous than the conventional SF model due to its ability to account for both inefficiency and full efficiency in a sample.

Our empirical results reveal that all key production inputs, i.e., fertilizer, labor, seeds, and land, are statistically significant and have a positive effect on maize output. In particular, we found that maize output is more responsive to fertilizer input than to other production inputs (i.e., seeds, land, and labor). In terms of determinants of technical inefficiency, we found that education, cooperative membership, extension services, access to credit, off-farm income, land tenure, and livestock ownership have a significant and positive effect on TE. Furthermore, the average TE of maize farms in our sample is estimated at 0.64, denoting that maize output can be improved by approximately 36% without increasing the proportion of farm inputs used. With respect to the relationship between farm size and TE, we find that on average, large-scale farms appear to be more technically efficient than both medium- and small-scale farms. Hence, this study provides evidence of a positive relationship between farm size and TE for maize production in Rwanda.

From a policy perspective, given our study finding that large-scale farms appear to be more technically efficient than both medium- and small-scale farms, land reforms such as land
consolidation should be encouraged to enhance aggregate production growth (Key 2019). The government and partners should devise initiatives and incentives for small-scale farmers to gradually leave the farming sector in rural area and join off-farm activities because small-scale farmers appear to be less technically efficient than large-scale farmers. In addition, efforts targeting enhanced efficiency and productivity might focus on improving rural financial services to help farmers obtain loans needed for their agricultural investments. Agricultural extension services might also be improved in terms of quality and accessibility to all farmers. Farmers must also be granted greater access to intensive agricultural resources such as inorganic fertilizers and improved seed varieties. In this regard, the input subsidy policy initiated by the Rwandan government is expected to play a significant role. Finally, our study suggests that future research should explore the effects of land and labor market imperfections on efficiency and productivity in the Rwandan agricultural production sector.
